There is certainly no necessity for this copying of titles, and it betrays a lamentable want of originality on the part of the originators of these journals that they should be forced to bestow borrowed names on their progeny. It is also at times confusing, and may lead to the giving of credit for good articles to the wrong journal. Nevertheless, we see no great crime in this appropriation of titles, for no harm can thereby result to the older journals after whom the younger ones are named. It is an evidence of appreciation and sincere flattery, so why take offence at it? The Medical Record has several namesakes, but it wishes them all well, and congratulates them upon the enjoyment of so aristocratic an appellation.

For the sake of peace, however, and in order to promote a fraternal feeling among our contemporaries, we would advise our young friend to change his name, and start life with a designation that will be all and entirely his own. We might, indeed, suggest a few names from which he could select the one that pleased him most. In the first place, the names of instruments furnish an inexhaustible source from which appropriate titles may be drawn. The *Lancet* and the *Scalpel* have been taken, but enough remain to offer a rich choice. We have the bistoury, the chain-saw, the forceps, the hypodermic syringe, the speculum, the catheter, and a host of others. Then there are other names relating more particularly to the avowed objects of the journal, such, for example, as the Occidental Boomer, the Western College Puff, the Missouri Doctors' Own, the Foe of the Atlantic, and many others. It would be allowable also to imitate, though not to copy, the title of some already existing periodical. Thus, instead of the name that it has so rashly chosen, it might be called the Relator of Medical and Chirurgical Facts and Fancies, or, in imitation of the *Medical Waif*, the St. Joe Foundling.

We extend to our young contemporary, whatever name he may be known by, the assurance of our most cordial consideration.

---

TREATMENT OF HYDRARTHROSIS OF THE KNEE BY SUBCUTANEOUS RUPTURE.

One of the most troublesome of all forms of articular dropsy to treat satisfactorily is chronic serous effusion of the knee. Why this is so is not so easy to explain—possibly it is because the effusion in this joint is apt to be greater than elsewhere, so that the lymphatics are unable to receive it with sufficient rapidity. However this may be, it is a fact that it is often impossible to disperse the fluid without recourse to operation, and, despite the comparative safety of operations on the articulations as practised in our day, it is nevertheless better to avoid even a puncture with an aspirator needle, if possible.

As a substitute for aspiration or a cutting operation in cases of hydrarthrosis of the knee which have resisted counter-irritation, pressure, etc., Dr. Georges Berne, of Paris, proposes subcutaneous rupture of the synovial membrane (*éclatement*), so as to promote the escape of the fluid into the surrounding tissues (*L'Union Médicale*, August 6, 1889). Examination of a knee-joint containing much fluid shows that fluctuation is most apparent at the upper and inner part, and if the joint be semiflexed the distended synovial sac will form a very distinct prominence in this situation. Dr. Berne's plan is to render this portion of the sac very tense by making upward pressure over the joint with the palm of the hand, so that a constricted neck is formed between the inner condyle of the femur and the concave border of the hand. The sac being thus rendered very tense, firm pressure is made upon it by the thumb of the constricting hand, or it is tapped somewhat sharply by the ulnar border of the fist of the other hand. By this means the synovial membrane is rent, and an escape of fluid takes place into the neighboring cellular tissues, where absorption readily takes place, owing to the abundant supply of lymphatics in that region. Resorption of the fluid is further aided by massage practised after rupture of the sac.

Dr. Berne has never seen any bad effects follow this procedure, and he recommends it especially on account of its safety and of its ease of execution. The method is, however, applicable only to comparatively recent cases, in which no marked thickening of the synovial membrane has taken place, and in which no evidences of inflammatory action are present.

---

Tuberculous Infection through Ear-rings.—A case is related in the *Wiener Medizinische Presse* of a young girl, fourteen years of age, of a perfectly healthy family, who wore ear-rings left to her by a friend who had died of pulmonary tuberculosis. Soon ulcers appeared on the lobes of both ears, the cervical lymph-nodules became swollen, and percussion revealed dulness at the apex of the left lung. Tubercle bacilli were found in the ulcers and in the sputa. It was presumed that the ear-rings were the agents of infection.

# News of the Week.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE held its annual meeting in Toronto, commencing August 28th. Professor Mendenhall, the President-elect, delivered an address of welcome. The first paper in the Anthropological Section was by Mr. Garrick Mallery, of Washington, and was entitled "Israelite and Indian—a Parallel of Culture in Planes of Culture." The general thought implied in the paper was an effort to show that there is a strong similarity between the Indian and Israelite races. An examination of the history of both races would show that they are on parallel planes of culture.

AN ACCIDENT IN A PHILADELPHIA HOSPITAL.—A painful accident, whereby several nurses were injured, occurred last week in the Philadelphia Lying-in Charity at Eleventh and Cherry Streets. Two strands of cable attached to the elevator broke and the car fell from the third floor to the basement. The elevator contained five nurses and the elevator boy, all of whom were more or less injured.

FOUNDLINGS AS FREIGHT.—The Russian Minister of the Interior has just issued an ordinance to all railway officials prohibiting the further packing of small children in baskets and forwarding them to the foundling-houses in the great towns as hand-luggage. The children were often packed as many as eight in one basket. The object of shipping the poor waifs in this way was to avoid the payment of fare, as it appears that the rules of the Russian railways always require payment for children of whatever age they may be.

THE PRINCE OF WALES is reported to be suffering from a mild attack of gout.

THE RIGHT TO PRACTISE MEDICINE IN BRITISH COLUMBIA.—An odd state of affairs exists in regard to medical practice in British Columbia, according to a correspondent of the *Lancet*, whereby Canadians as well as Americans are discriminated against in favor of those educated in Great Britain. It appears that during the last session of the Local Parliament a number of medical acts were consolidated, and among them an act of 1866 which was thought to have been repealed. Consequently, as the law stands at present, only men with British diplomas have the right of practising in the province without examination. All others, Canadians and Americans alike, have to pass an examination, and have moreover to pay a hundred dollars to the Provincial Medical Council.

LATE PREGNANCIES.—A correspondent writes for definite information regarding late pregnancies. Can any of our subscribers give cases of fifty years of age and over?

TYPHOID FEVER ON A TRAINING-SHIP. — There is a slight epidemic of typhoid fever on the United States training-ship New Hampshire, and a number of cases at the Newport Hospital. Investigations into the cause are to be made by a board of naval surgeons.

THE USE OF COSMETICS IN BERLIN.—Some statistical fiend says, concerning the women of Berlin, that they use every day over 400 pounds of face powder, 250 pounds of rouge, 125 pounds of eyebrow-paint, 100 pounds of lip-salve, and 50 pounds of cold cream.

THE INTERNATIONAL PRISON CONGRESS will be held in St. Petersburg in the summer of 1890. A prize of $400 is offered by the conductors of the *Prison Discipline Review*, for the best essay on the subject: "What in the most civilized nations has been the historical development of the institutions relating to the correctional education of minors who have been convicted of crimes at common law, or who have been put in custody for idleness and vagabondage, or with a view to paternal discipline?" The essays must be written in Russian or French, and must be sent to "The President of the Organizing Committee of the Fourth International Prison Congress, at St. Petersburg," not later than May 15, 1890. They must be furnished with a motto, and accompanied by a sealed letter containing the writer's name and address.

TYPHOID FEVER IN LONDON.—There has been something of a fever scare in the West-end in London, a number of cases of typhoid fever having occurred there during the past few weeks. The disease was of a mild type, but it was remarkably wide-spread, a number of cases appearing almost simultaneously in different houses scattered over a wide district. It is thought that milk was the means of spreading the contagium.

ENGLISH PHYSICIANS IN SWITZERLAND.—The Swiss Government has refused to allow foreign physicians to practise in that country, and even forbids apothecaries to dispense any prescription written by them. This action is aimed more particularly at the English medical men who have followed their patients to the Swiss resorts, and have sought to obtain a practice among the English residents. The action of the Government is said to have been taken at the instigation of Swiss physicians residing at the popular health-resorts, and who did not relish the idea of having the cream of their practice taken from them by foreigners.

THE SIXTY-SECOND CONGRESS OF GERMAN PHYSICIANS AND NATURALISTS will meet at Heidelberg on September 18th to 23d. Several foreign medical men have been invited to take part in the proceedings of the Congress.

DR. THOMAS KING CHAMBERS, of London, died in that city on August 15th. He was honorary physician to the Prince of Wales, but had not been in active practice for a number of years. Dr. Chambers was the author of several articles in Reynolds' "System of Medicine," and had also published several works on subjects relating chiefly to diet and diseases of the digestive organs.

DR. JOHN T. BANKS, of Dublin, has been created a Knight Commander of the Order of the Bath.

THE SECOND ITALIAN CONGRESS OF INTERNAL MEDICINE will be held in Rome on October 15th to 17th. The chief subjects for discussion will be gout, nephritis, and malaria.

A NEW TRI-STATE MEDICAL ASSOCIATION.—A call has been issued to the members of the medical profession in Alabama, Georgia, and Tennessee, to meet in Chattanooga on the third Tuesday in October, for the purpose of forming a Tri-State Medical Association. All will be admitted to the meeting of the Association, but the membership will be restricted to graduates of regular medical colleges in good standing. This call is signed by committees from Jackson County, Ala., Medical Society;

Chattanooga, Tenn., Medical Society; Cleveland, Tenn., Medical Society; Cartersville, Ga., Medical Society; Dalton, Ga., Medical Society. The organization will be independent of all other societies. It will be an association of individual members of the profession of medicine, and will be managed in the interest of medical progress. The session will continue two days. Those desiring to read papers or exhibit specimens are requested to notify the secretary of the committee, Dr. F. T. Smith, of Chattanooga, Tenn., at an early date.

THE ANATOMICAL SOCIETY OF GREAT BRITAIN held its annual meeting on Thursday, August 15th, in Leeds. Dr. Ambrose Birmingham succeeded, by following the nerve-trunks, in ascertaining that an extra lumbar vertebra belonged to the sacrum and not to the dorsal region. Drs. Griffiths and Oliver, having observed that the distribution of herpes zoster seemed irreconcilable with current accounts of the anatomy of the spinal nerves, were led to investigate their anatomy. They showed that the dorsal branches of the spinal nerves were distributed to the skin very much lower than is supposed, and that they ran downward for some distance in the substance of the muscles. They also presented a series of specimens and frozen sections from the Leeds Museum, showing a patent parumbilical vein, an anomalous round ligament of the liver, feet with six toes, frozen sections of the pelvis. Dr. R. W. Reid also sent some rare specimens of cervical ribs, a fifth lumbar vertebra with a suture in the neural arch between the upper and lower articular facets. Messrs. Lockwood and Withers showed an unusual right aortic arch, which, while showing the usual condition, had persistence of a part of the second left arch, which gave off the left subclavian artery. Professor Alexander Frazer showed a series of photographs of anatomy, histology, and embryology. He also described some bodies like Pacinian corpuscles, which he had found in the thyroid gland, and in giving the details of his work on the spinal cords of a number of rodents, said that he found that the pyramidal tract ran in the posterior columns of the cord, and not as others had described.

INTERNATIONAL MEDICAL CONGRESS.—A further announcement concerning the Congress has been made. Membership is limited to physicians and surgeons in regular standing. The registration fee is twenty marks, and each member will receive a copy of the Transactions. The purpose of the Congress is purely scientific, and its business will be transacted in sections. In the first sittings of the various sections a president and a sufficient number of honorary presidents will be elected, the latter to preside alternately with the former. Owing to the difference of languages, a sufficient number of secretaries will be appointed from among the foreign members. The general sittings are intended for debates regarding the work and general relations of the Congress, and for addresses and communications of general interest. Such addresses are to be delivered only on invitation of the Committee of Organization. Proposals relating to the work of the Congress must be made to the said committee before July 1, 1890. The committee will decide whether they shall be adopted or not. All discourses and communications in the general and in the sectional meetings must be delivered to the secretaries in writing before the close of the sitting. The Editing Committee will decide whether and in what compass these writings are to be printed in the Transactions. The official languages used at all meetings will be German, English, and French. The by-laws and programmes will be printed in all three languages. Introductory discourses in the sections are to be limited, as a rule, to twenty minutes; in discussion only ten minutes are allowed to each speaker. Students of medicine and other persons of both sexes who are not physicians, but feel interested in the debates, may attend the sittings on permission being obtained from the president.

ACETOPHONE.—Acetophone, or methyl-phenyl-ketone, which has been employed chiefly by some French physicians as a hypnotic, has recently been studied by Dr. S. S. Kamenski ("St. Petersburg Dissertations," No. 70, 1888–89) in the laboratory. He finds that it lowers sensibility and interferes with reflex action. Large and medium doses produce a moderate amount of sleep. It quickens the heart's action, probably by stimulating the accelerator nervous apparatus. It increases the irritability of the respiratory centre, except in large doses, which may arrest respiration altogether. It lowers the blood-pressure by its action on the vaso-motor centre, and by weakening the heart's action. Medium and large doses lower the irritability of the brain, and even small doses have a similar effect on that of the cord.—*Lancet.*

YOUNG MEDICAL STUDENTS.—A correspondent of the *Hospital Gazette*, writes from Glasgow that the average medical student seems to begin his work very early nowadays. Of the students who had completed their curriculum here, several were compelled to wait a year for their examination on account of their age, while no less than a dozen who had just passed the final "exam." would not be able to graduate for six months, until they should attain their majority.

RECIPROCAL TRANSFUSION IN TYPHOID FEVER.—A writer in the *British Medical Journal* suggests the treatment of typhoid fever by mutually transferring the blood of a person with the disease and that of one who has already passed through an attack. He reasons that in this way the bacilli will be destroyed by having no more pabulum upon which to feed, while the healthy individual, already enjoying an immunity, will not suffer. This seems to be the season for queer notions in medicine.

THE DIAGNOSIS OF PERFORATION OF THE DRUM-MEMBRANE.—Dr. Spear proposes the following method for detecting minute perforations of the drum-membrane: While looking into the auditory canal in the ordinary manner, with speculum and mirror, hold a piece of cold glass close to the speculum, have the patient do the Valsalva experiment, and if a perforation exists the vapor of the breath will be condensed upon the glass and obscure the view.—*Boston Medical and Surgical Journal.*

PROFESSOR V. BERGMANN, of Berlin, has recently received from King Humbert the grand cross of the Italian Order of the Crown. During the recent visit of the King of Italy in Berlin, one of his officers was seriously injured at a review, and was treated at the special request of Emperor William by v. Bergmann, and this decoration was his reward for having brought the case to a successful issue.

# Society Reports.

## BRITISH MEDICAL ASSOCIATION.

(Special Report for THE MEDICAL RECORD.)

*Fifty-seventh Annual Meeting, held at Leeds, England, August* 13, 14, 15, *and* 16, 1889.

(Continued from page 246.)

### THURSDAY, AUGUST 15TH—THIRD DAY.

THE PRESIDENT said that a resolution had been adopted, by the Section in Public Medicine, having for its object an improvement in the public health service, which had been referred to the general body for approval. The resolution was unanimously approved.

MR. T. PRIDGIN TEALE then delivered the Address in Surgery (see p. 232), taking for his subject

DETAIL IN SURGERY.

At the conclusion of the address a vote of thanks was moved by DR. MACEWEN, who said that he had learned a great deal of surgery during his visit to Leeds. The name of Teale was one which was known throughout the surgical world, father and son having contributed largely to surgical science. Mr. Teale's accomplishments were not confined to surgery, but included the most delicate operations upon the eye. He also devoted a considerable amount of time to sanitary subjects, and had made himself an authority on the economy of coal.

DR. MITCHELL BANKS seconded the motion, remarking that he should like to be able to express to Mr. Teale the sentiments of respect and admiration with which they regarded him as the type of all that was best in British provincial surgery. It was given to some to excel in one department of the profession, but to excel as an operating surgeon, and to take rank as an oculist, and to be foremost among the sanitary scientists of the country was given to very few.

The resolution was adopted unanimously.

AN INQUIRY INTO THE MANAGEMENT OF MEDICAL CHARITIES.

THE PRESIDENT then gave notice of the following resolution, which would be moved at the next session:

"That this meeting of the British Medical Association views with great pleasure the action of the Charity Organization Society of London in presenting a petition to the House of Lords praying for an inquiry into the management of the metropolitan medical charities, and earnestly hopes that the scope of the inquiry will be extended so as to include provincial hospitals and dispensaries, with the view of obtaining as complete information as is possible upon this important subject; that a copy of this resolution be forwarded to the Lord President of the Privy Council, and that he be requested to receive a deputation; that the Council be requested to appoint a special committee to deal with the question, and request the Charity Organization Society of England to form a similar committee to act in conjunction with it."

In the evening the members of the Association and of the profession, of Leeds, met at a banquet which was given in the Town Hall.

### FRIDAY, AUGUST 16TH—FOURTH DAY.

SIR JAMES CRICHTON-BROWNE delivered the Address on Psychology, taking for his subject

THE HYGIENIC USES OF THE IMAGINATION.

A large part of the burden of caring for the insane fell upon the general practitioner, for many of the mentally afflicted were now treated privately instead of being cared for in asylums. It was true that there were

EIGHTY-FOUR THOUSAND FOUR HUNDRED AND SEVEN INMATES OF INSANE ASYLUMS

who were under the care of specialists, yet nearly all had been consigned there on the evidence of medical men who were not specialists. A bill recently passed in Parliament, and now awaiting the royal assent, would in a measure relieve medical men from much of the apprehension which they now felt in signing lunacy certificates, but nothing could take away the sense of responsibility which they must necessarily feel in thus depriving any person of his freedom and entailing upon him sure opprobrium as well as far-reaching disabilities. The certification of insanity must, therefore, always remind the general practitioner that psychology is a subject of especial and practical interest to him. But it was not here alone that medical psychology came into prominence, for it met the general practitioner at every turn, and in his daily practice.

An address such as the present might emphasize the psychical side of the union of mind with matter. The researches of many physiologists led to materialism, but mind was not a mere exhalation of brain-substance. Materialism was an error—confusing the objective with the subjective. To describe consciousness as a function of the brain was erroneous. Volition, cognition, and feeling were not functions of the brain. The real nature of the relation between mind and matter was unthinkable. Various theories had been suggested; as, that the psychical relation of mind to the brain was that the mind acted through the nervous system; that the brain and mind were simply the reverse, one of another; and that there was a parallel between mental states and states of the brain (theory of parallelism or concomitance). The latter view was that held by Herbert Spencer, Tyndall, and Hughlings Jackson. The psychical centres had been placed in the prefrontal lobes. Electrical stimulation of these lobes in monkeys had led to the belief that they were not motor. But the psychical centres could not be pent up in any part of the brain. Trousseau had related the case of an officer whose frontal lobes had been pierced by a bullet without any sensible loss of intellect, and he had himself conversed with a man from whose right hemisphere Professor Horsley had taken a tumor the size of a goose's egg, and in whom he could detect no mental defect.

Confining his remarks, then, to one of the mental faculties, imagination, the speaker said that it had an application in the treatment of disease which neither the general practitioner nor the specialist could afford to neglect. This psychic power was like a pioneer in a new country, for

IT OPENED UP NEW PATHWAYS IN THE BRAIN,

by means of which its different territories were brought into closer and more ready communication. The brain, without imagination, was like a country without railways, in which locomotion was laborious and slow; and the brain richly gifted with it was like one in which steam and electricity had established easy and rapid communications. He would not stop to trace that development of imagination which, resting upon intuitive beliefs and historical facts, and stirred by the most earnest cravings of our nature, mounted into faith and revealed to man "the substance of things hoped for, the evidence of things not seen." Neither could he devote much of the time at his disposal to those

EXCRESCENCES ON FAITH

known as Christian science and faith-healing, which had a certain vogue at present, and fell legitimately within the scope of medical inquiry. It was not to be gainsaid that faith, even in its aborted or degenerated phases, had a potent effect on the human organism, and was capable of relieving and removing certain functional disorders; and credit might therefore be given to faith-healing and Christian science for some of the cures which they claimed. Their professors, like empirics of all sorts, had wrought modern miracles on hypochondriacal men who had fallen into drivelling egotism; on hysterical girls who had entertained demons, not unawares; and on a few sincere but highly sensitive persons who

could pass at a touch out of one allotropic state of the nervous system into another. But the small good they had done these had been more than counterbalanced by the mischief they had wrought in encouraging imposture, in postponing medical treatment where it was needed, and in inducing in their adherents an attitude of mind that was debilitating and conducive to the incursion of disease. Before faith-healers and Christian scientists could claim a hearing, they must learn how to make an accurate clinical report, apprehend what induction really meant, and abandon the baseless assertions in which they at present dealt. Only impatience and contempt came to the medical man who perused their pretentious archives of cures in cases in which disease was evidently simulated, in which it ran its natural course, in which its existence was asserted, no proof being given, or in which it was of a purely subjective character, and might or might not depart at the word of command—such archives being, in one or two instances, accompanied by minute directions as to how post-office orders are to be forwarded. Let the faith-healers and Christian scientists, he said, commence with skin diseases—lure the acarus scabiei from its burrow without the aid of sulphur, arrest lupus, and wipe out a nævus—and then their claims of power to cure internal diseases might be listened to with some respect. But it was not of faith, or of this travesty on faith, that he had to speak. The subject of his remarks was simply imagination,

SECULAR IMAGINATION,

he might call it, which was one of the most effectual of those psychical agencies by which the conditions of health and of disease might be modified. He would consider especially the hygienic uses of this mental faculty, though a word might be said as to its scientific use as an instrument of discovery in investigations of disease, both particular and general. Medical men had not merely to identify and catalogue the symptoms of disease, but they had to trace them to their antecedents and true causes, and this they could only do by invoking imagination's help to supply them with speculations and hypotheses, which were not less essential to them in their work than the microscope, test-tube, and clinical thermometer.

ALL TRUE SCIENCE RESTS ON IMAGININGS,

he said, and is nothing else than a body of established truth which imagination has built up. Observed phenomena had to be explained by unfolding their causes; and in medical inquiry a provisional guess was hazarded, which was then put to the test by further observation and experiment. Of course, such provisional guesses were often wrong, and then had to be given up. But all the truths of science had been provisional guesses to begin with—working theories formulated by the imagination, and proved by the touchstone of experiment, and so brought to a mathematical certainty.

The cultivation of the imagination was most important to medical men, and they need not fear that they were wasting their time when they turned aside now and then from their pofessional tasks to ramble for a little in the green pastures of literature. Imagination might be fully trained for its professional duty, as it was exercised, in conjunction with observation and judgment, in the scientific sphere; but it would be braced, invigorated, and have its resources multiplied by recreating occasionally in its native air. Even if imaginative pursuits did not strengthen the hands of medical men in grappling with disease, or quicken their scientific vision, they would still be commendable because of the refreshment they bring to jaded brains. To turn from the fatigue and anxieties of practice into realms where rivalry was no more and night-bells never rang, was to plunge into one of the most soothing and depurative of

TIRED NATURE'S BATHS.

Members of the medical profession were, indeed, generally aware of this, and resorted to imaginative literature, music, and art more than any other class of professional men, except, of course, artists and men of letters, and to an extent that was remarkable, considering the engrossing claims made on their time and the scant leisure they enjoyed. Having referred to some of the contributions of medical men to the department of imaginative work, the speaker said that it was not as producers, but as consumers of poetry and imaginative literature, that they derived from them their restorative influence. It might be objected that the imagination, if sometimes stimulating and restorative in its influence, was often morbid in its tendencies, and that its indulgence was to be guarded against by those who desired to possess well-regulated minds. But the weak vessels wrecked by imagination were really fewer than was commonly supposed; and he did not hesitate to say that there were a dozen cases of

INSANITY CAUSED BY WANT OF IMAGINATION

for one caused by excess of it. Apathetic dulness and torpor of mind were apt to deepen into dementia; and those entirely given up to "the care of this life and the deceitfulness of riches" were more likely to be choked by them than those who could surmount them, and breathe the free and ample air of æsthetical emotion. A vulgar error as to the nature of insanity had perhaps conduced to exaggeration as to the dangers of imagination. Visitors to asylums invariably expected to find growths of morbid invention and belief, wild, tangled, and luxuriant as a tropical forest, and left much disappointed by the barrenness of the land, for the insane were the least imaginative of beings. Idiocy was the absolute negation of imagination, and insanity undermined and destroyed or enfeebled it more or less; and, when they tried to drive out insanity, the first thing they did was to invoke imagination's aid, for moral treatment consisted mainly in appeals to this faculty, and fully acknowledged its hygienic uses.

THE FIRST RECORDED CURE OF MELANCHOLIA

was by the harp of David, and to-day in every lunatic hospital worth the name persistent efforts were being made by music, by pictures, by poetry and the drama, to stimulate the imagination, and thus "cleanse the stuffed bosom of that perilous stuff that weighs upon the heart." Like every good gift, imagination might be prostituted and abused, and in the history of art, literature, and the drama, abundant proof might be found that it had been made to pander to vice and folly. But when this had been the case, it was not so much the imagination that had been at fault as a certain pestiferous element that had been infused into it. The records of crime, when reported with prurient detail, and with a halo of romance thrown round them, had sometimes a permanently pernicious effect, and tended to reproduce themselves.

MEN OF TASTE TURNED FROM SUCH GARBAGE WITH DISGUST,

but there were always sickly and partially depraved natures ready to be powerfully affected by strong impressions of a criminal complexion. Sheer weakness and vacuity or instability of temperament are the soils most congenial to vicious and atrocious ideas. A highly and widely cultivated imagination seems to increase physiological resistance to morbid and profligate suggestions, and also to pathogenic germs, for in plague and pestilence those are most likely to escape who have varied mental resources, can distract their minds and look beyond the moment, and those are most likely to succumb who give themselves up to abject fear.

The speaker then referred to the

INCREASING PURITY OF ENGLISH LITERATURE,

which was so noticeable at the present time, and pointed out the absolute necessity that existed for the preservation of the literature for the young from any taint of impurity, since impressions made at this time were indelible and would influence the whole future of the individual. The study of statistics of public libraries had brought out

one fact that was most interesting to medical men. This was that the call for works of fiction and volumes of poetry was greatest in the spring, when nervous erethism existed, and "a young man's fancy lightly turns to thoughts of love," and was least pressing in autumn, when the nervous system was comparatively quiescent. In concluding his address, Sir James Crichton-Browne said that he had endeavored to unfold before his hearers some of the uses to which imagination might be put by the medical man, and he would only repeat now the assertion that imagination must always receive primary consideration in a study of mental hygiene.

After a vote of thanks had been extended to the speaker, a number of resolutions were introduced, among others, the following upon the

DISPOSAL OF TOWN-REFUSE,

presented by the Section in Public Medicine.

1. That this meeting hereby expresses its disapproval of any system of middens, sewers, cesspits, dust-bins, etc., which involves the storage of filth or house-refuse in the immediate neighborhood of dwellings.

2. That it further considers that in towns, villages, and other populous places the sanitary authority should itself undertake the removal of such refuse from each household at frequent, regular, and, in populous places, daily intervals, at the public expense, without waiting for notice to be given by the householder.

3. That it expresses its preference for small movable, water-tight receptacles for the collection of house-refuse or other excreta, in order to fill the essential conditions of preventing pollution of soil as well as air.

THE PRESIDENT then proposed a

VOTE OF THANKS

to the citizens of Leeds for the very handsome manner in which the Association had been received and entertained. After a vote of thanks to the President had also been passed, the meeting was adjourned.

---

## SECTION IN PUBLIC MEDICINE.

WEDNESDAY, AUGUST 14TH—FIRST DAY.

DR. EDWARD BALLARD, President of the Section, opened a discussion on

MEDICAL OFFICERS OF HEALTH.

He dwelt especially upon the requisites for an efficient medical health-officer. In the first place, he should be possessed of that kind of learning which should fit him to deal with and to advise about disease as it affects the community rather than as it affects the individual.

Since, however, communities are made up of individuals, a knowledge of disease as it affects individuals is the basis of the knowledge of disease as it affects communities, and this is the reason why an officer of health, to be efficient, must be a medical man "Nihil humanum a me alienum puto" is the motto which every practitioner of the art of medicine appropriately adopts; "Nihil mundanum a me alienum puto" should be the motto of every medical officer of health.

Secondly, he requires practical training under the direction of a good health-officer, just as the practising physician needs hospital training. Finally, they should be possessed of tact, and this was of equal importance to the rest, for without it the other qualifications would be practically useless. Health-officers had many things to contend against, and their troubles were neither few nor light, but their burden would press less heavily upon them if they would seek consolation in scientific studies.

Nature is never unkind to such as in the proper way seek to learn her secrets; she never disappoints, never vexes, never discourages. To the medical officer of health working in the baldest rural districts, as well as to him who labors in the crowded town, she holds an open gate, and says, "Treasure is hidden here; my servants are contented and happy; come and dig."

DR. C. E. J. GREENE was unable to be present, but sent a paper upon some of the difficulties in the way of an efficient carrying out of the sanitary officer's duties. He suggested that medical officers of health should possess a diploma in sanitary science, obtained by passing a Government examination in analytical chemistry, botany, geology, pathology, and sanitary engineering; should hold jurisdiction over a large area; be appointed by and draw their pay from Government, which pay should be sufficient to support them without their engaging in any other occupation; should not engage in private practice; and should have the option of promotion to a better district after some years' service.

DR. CALDWELL SMITH thought that

TOO MUCH ANALYTICAL CHEMISTRY

was required of medical officers. Although they should know something of the subject, it was not necessary for them to pass six months in an analytical laboratory, nor did he think it advisable that they add the duties of a public analyst to those of a health-officer.

DR. LITTLEJOHN agreed with the last speaker as to the unadvisability of combining the public analyst and the health-officer in one person. He thought there should be a rule forbidding medical officers of health from engaging in private practice.

Several other speakers took part in the discussion.

MR. J. B. JAMES read a paper advocating the appointment of

A CABINET MINISTER OF PUBLIC HEALTH.

DR. GARROD spoke against

SENDING PATIENTS TO FOREIGN HEALTH-RESORTS.

He stated that a committee had been appointed by the Royal Medical and Chirurgical Society for the purpose of seeing what could be done at the different bathing places in England, Wales, and Scotland in the treatment of cases which now usually went abroad.

MR. R. C. APPLETON contended that consumptives were just as much benefited in going to some of the sea-coast places in England as to the Continent. It has not been proved that the climate of this country could not do as much good as continental places; hence he thought the members of the Section should make a strong stand against the practice of leading medical men who sent patients to the Continent without any results superior to those which were obtainable in our own country.

MILK AND TYPHOID FEVER

was the subject of a paper by DR. ANDERSON, of Dundee. He observed that in February, March, and April last, an outbreak of typhoid fever occurred among the customers of one particular dairy in Dundee, and the most searching inquiries failed to find any trace of disease among the persons handling the milk or in their households. He was satisfied this milk did not acquire-infection from the human subject. The sanitary inspector and himself examined the teats and udders of all the cows which supplied the suspected milk. On one of the cows they found an eruptive disease on each of the four teats, presenting the appearance of ringworm, level in the centre, the margin raised, thickened, and excoriated, without scab or crust or infiltration of the base; the eruption on the inner side of the left hind teat being nearly circular, and about the size of a shilling; those on the other teats being apparently of longer standing, and encircling the whole teat, so as to present, not a circular eruption, but a raised, thickened, freely excoriated edge. There was no eruption on the udder nor on the body. The cow appeared to be in perfect health, with a fine coat.

DR. CALDWELL SMITH did not see that any causal relation between the eruption on the cow's teats and the outbreak of typhoid had been proven.

Dr. T. Churton presented a communication entitled

INSANITARY HOUSES IN LEEDS,

in which he detailed the results of a systematic inquiry into the sanitary state of the homes of hospital patients. About one house in five was found to be in a decidedly insanitary state. He thought that the inspection of the dwellings where patients in hospital had lived was a matter of considerable importance, and should be more systematically made.

---

Thursday, August 15th—Second Day.

Dr. Parsons read a paper on

DISINFECTION WITH REFERENCE TO THE CONTROL OF EPIDEMICS.

By disinfection, he said, he meant the destroying of the activity of that matter which, produced by a sick person and received into the system of a healthy one, had the power of causing in the latter a disease similar to that from which the former was suffering. Modern research had shown that certain diseases in men and animals were undoubtedly caused by the presence in the system of micro-organisms that were communicable by the inoculation of such organisms. Of the pathogenic microbes the most convenient for the purpose of testing disinfecting agents was the bacillus anthracis. It formed, under certain circumstances, spores which were exceedingly tenacious of life; it could be cultivated, and was easily recognized both by its microscopic character and its appearance when growing, and if inoculated into animals it produced in them with certainty the disease known as anthrax. None of the ordinary infectious diseases of mankind were known to be caused by spore-bearing microbes, though it was possible that small-pox, the contagium of which was very tenacious of life, might turn out to be so; and so far as their present knowledge and experience went, they might assume that means which would destroy the spores of the bacillus anthracis might be relied on as efficacious for their purpose, though it would not follow that agents which did not destroy bacillus anthracis were therefore useless against the less resisting contagia of other diseases.

The speaker then referred to various experiments to determine the

BEST MEANS OF DISINFECTION.

It had been shown that steam would destroy the pathogenic micro-organisms much more quickly and more surely than dry heat. Carbolic acid and sulphurous acid gas were efficacious to a certain extent in destroying the vitality, or at least retarding the growth, of bacteria, but bichloride of lime was the best disinfectant when it could be employed. The matters which might act as carriers of infection, and might thus require disinfection, were: 1. The body of the patient, living or dead. 2. The discharges given off from the body of the patient, and more particularly those from the organs specially affected by the disease. 3. The air, tainted by exhalations from the sick, and the poison probably existing therein in the form of suspended particles. 4. The clothes, bedding, and other textile articles used by the sick. 5. Utensils of various kinds used by the sick. 6. Articles of food, as milk and water. 7. Walls, floors, etc., of dwellings occupied by the sick, especially dust and dirt lodging upon the walls, and dirt accumulating in the cracks of the floor. 8. Collections of filth, as sewage, especially in a stagnant state, or deposited in or encrusting the sides of foul drains, foul ground surfaces, and subsoil. It was not of much use attempting to disinfect the infected air of sick-rooms by chemical means, for active chemicals, if present in sufficient quantity to be effective as disinfectants, would render the air irrespirable. It was easier to get rid of it, and let its place be taken by fresh air. The contagia of most infectious diseases appeared to be destroyed when fully diluted by fresh air. The poison of typhus fever was notably so, but that of small-pox did not appear to be, and it had been proposed that, instead of ventilating small-pox wards into the open air, the air from them should be extracted through a flue and burnt in a furnace. Or, he might suggest that a steam-blast might be used to extract the air and disinfect it at the same time. Of chemical disinfectants for the disinfection of excreta, corrosive sublimate, probably, is the most trustworthy and suitable for ordinary use.

For most cases of disinfection, either dry or moist, heat could be used, but leather was destroyed by steam. Books could be disinfected by means of dry heat, the leaves being spread open. For

HOUSE DISINFECTION,

fumigation with sulphurous acid or chlorine gas, the latter preferred, followed by thorough cleansing and scrubbing, the removal of wall-paper and whitewashing, were to be recommended; but these processes, to be effectual, needed to be carried out with more thoroughness than was often done.

Dr. Caldwell Smith spoke of

THE NECESSITY OF ISOLATION

as well as disinfection. The latter was often very thoroughly carried out, while no attention at all in many cases was paid to the former. He advocated the establishment of cottage hospitals, in rural districts, as well as in towns, and said that all cases of zymotic disease should be removed to the hospital. It would be necessary, however, to teach the public before the need for this strict isolation would be realized.

Dr. W. Squire also referred to the great value of isolation in the prevention of epidemics. The disinfection of premises, rooms, and clothes, which followed upon the removal of the sick, often prevented other cases arising from the same source, while the removal of the patient for the whole period of infection was a more efficient safeguard against its spread than any amount of soap and water or external disinfectant could possibly be. Both means should be in force, but it was useless to give notice of the presence of infection unless means of isolation were provided and insisted on; no method of disinfection would succeed unless those who had been exposed to infection were kept from mixing with others, at school or elsewhere, until they were known to have escaped it, and those who had been attacked were kept from mixing with the susceptible until the infectious period was over. The results of this system of isolation were very clearly shown in the lessened mortality of scarlet fever during the epidemic in 1887. In that year the disease in London was less fatal than in many non-epidemic years, and so completely was it arrested, that for the first time since registration began, no autumnal increase of it occurred at the end of the last year.

Dr. E. W. Hope cited several cases in which neglect to isolate and disinfect had been followed by disastrous results.

Dr. C. H. Allfrey read a paper on

INFECTIOUS DISEASES IN HOTELS,

in which he gave an account of an outbreak of scarlatina, which occurred while he was acting as resident physician at the Grand Hotel, Grasse, and laid stress on the importance of extreme caution in giving advice as to infection from mild cases, holding that it was only safe to treat all cases, however mild and whatever their stage, as equally infectious, believing that infection depended more on the susceptibility of the patient and on the degree and circumstances of the exposure, than on the severity or stage of the infecting case. He expressed an opinion, that a second outbreak which occurred in the hotel would have been prevented altogether had the removal from the hotel of the whole of the infected family been insisted upon. He thought that the importance of adopting such a course upon similar occasions should be impressed upon all hotel-

keepers. He advocated the formation of an association of hotel-keepers, having for its principal objects (1) an agreement to insist upon the removal from their hotels (as soon as practicable and convenient with the safety of individuals) of all members of an infected family; (2) an agreement to require the signature of all visitors to a declaration that none of the party had been suffering from, or, to their knowledge, exposed to, infection within a certain period; (3) the establishment of a register of sanitary certified hotels. He warmly advocated the non-concealment of the occurrence of infectious cases, both as a matter of justice to the visitors and as a matter of policy to the proprietors. He believed that visitors in a hotel where the existence of infectious disease was known, and where they could see what precautions were taken, and gauge the degree of danger, were safer than in chance hotels, where cases of infectious disease might be concealed.

Dr. Hutchinson stated that he had charge of the recent outbreak of scarlet fever at Monte Carlo, and with regard to the hotel arrangements he experienced exactly the same difficulties as Dr. Allfrey had described. The present mode of disinfecting rooms after scarlet fever was absolutely useless, as was proved by a case which came within his experience at Monte Carlo, where a young man, after sleeping in a thoroughly disinfected room, occupied three weeks previously by a patient, caught the fever and died. They should have villas of isolation, and next year he hoped that some institution of that kind would be provided at Monte Carlo for the reception of cases as they arose at hotels.

Dr. Littlejohn thought the villa system was impracticable, but favored the establishment of a hospital for contagious diseases in every city. In Edinburgh there was a hospital of this kind in which the well-to-do as well as the poor sought care and treatment whenever they were suffering from any contagious disease.

At the conclusion of the discussion the Section adopted a set of resolutions embodying the suggestions made by Dr. Allfrey.

Dr. Greenwood then read a paper upon the

DISPOSAL OF TOWN REFUSE,

in which he urged the necessity of covered wagons for the removal of waste matters.

Dr. Slade-King said that combustion was the only practicable method of safely disposing of house refuse.

Other papers were read dealing with the same subject and suggesting better methods of disposing of waste matters than those now in use, and a committee was appointed to draw up resolutions expressing the views of the Section on this point.

---

Friday, August 16th—Third Day.

Dr. Greenwood, on behalf of the committee appointed to draft resolutions on the disposal of town refuse, reported that a set of resolutions had been adopted and would be presented to the general meeting of the Association for approval.

Dr. J. T. Arlidge presented a communication entitled

THE SOURCES OF LEAD-POISONING IN THE ARTS AND MANUFACTURES.

This metal exerts its poisonous influence under three forms, namely—1, lead in the solid form, as lead ore, as metallic lead, and as an alloy; 2, in the form of its salts, whether in powder or solution; and 3, in a mixed form, with oils and fluxes. In the form of ore it is productive of plumbism among the miners and smelters, being injurious to the former chiefly in the shape of dust, and to the latter in that of vapor. It is, too, as a vapor that it produces its noxious effects among the makers of the oxides of lead in the process of calcination. In the case of metallic lead, plumbism is a result among those who frequently handle it, such as file cutters, makers of leaden pipes and of shot and lead foil, plumbers, and type-casters. In type it enters as an alloy, and as such at times affects injuriously compositors. In the shape of an alloy it proves mischievous with pewterers, the makers of soft metallic capsules, and of inferior German silver or pinchbeck. Further, metallic lead becomes indirectly the cause of illness when employed to form utensils for the storage or preparation of articles of food or of snuff and tobacco, or in the construction of pipes for conducting or drawing off fluids. But cases of poisoning are caused more frequently by salts of lead, especially white and red lead. The writer also referred to the accidental introduction of the metal, in articles of food or in drinking-water, under conditions so well studied by sanitarians; in porter, beer, cider, and lemonade, or fruit juices, any of which may have stood in contact with lead or its alloys in the form of pipes or capsules; or in bottles carelessly cleaned with shot; in solid, but moist or deliquescent, food preserved in lead-foil, or so-called tin cans with soldered joints; or in food cooked or salted in vessels on the surface of which lead occurs as a glaze, or else which have it enter into their structure.

Dr. Arlidge then read a second paper, entitled

THE OBSERVATION AND RECORDING OF THE EFFECTS OF OCCUPATION UPON HEALTH.

Among the causes of disease, he said, the effects of occupation were not generally enough recognized, and, indeed, they had not yet been sufficiently studied.

To establish the study of industrial disease upon a sound footing it was necessary to ascertain the numbers engaged in a manufacture, the diseases occurring among them for a series of years, the character of those diseases, and the conditions of employment and the materials used in performing it. The inquiries to be presented were, therefore, of a four-fold character, viz., statistical, pathological, technical, and sanitary.

Dr. Sinclair White read a paper on the

CONTAMINATION OF DRINKING-WATER BY LEAD.

The measures which are of efficacy in preventing contamination, or in removing lead already present, were of three kinds. First, those in which lead piping and lead-lined cisterns are replaced by other materials, such as wrought-iron, tin, and glass-lined iron. These are most applicable in the case of new houses; and wrought-iron piping might be much more utilized than it is for this purpose. Secondly, removal of lead from the water. Nearly all forms of charcoal filters will do this most effectually. Thirdly, treating the water before distribution so as to do away with its solvent action. The last named is the most desirable way of combating the evil, but it is the most difficult to carry out.

Dr. T. B. Fairclough followed with a paper on the same subject. He believed that much of the anæmia and physical degeneration apparent in large towns was largely due to the constant drinking of small quantities of lead, the amount of lead palsy and lead colic being by no means a true indication of the real amount of lead-poisoning in any district. Soft waters were those to be avoided, and the water most fit for drinking purposes was spring water, of sufficient hardness to prevent its taking up lead under any circumstances.

Dr. Jessop read a paper on

THE NUTRITIVE VALUE OF FOOD,

in which he pointed out the advantages resulting from care in the preparation and cooking of various kinds of food.

Mr. Johnson Martin presented a communication upon

THE CARE OF LIVE STOCK AND ITS INFLUENCE UPON THE FOOD-SUPPLY.

He said that cattle were not cared for as well now as in former times. For example, the high embankments

which formed shelter from heat and cold for animals had been and were still being taken down, causing pleuro-pneumonia and kindred diseases. It would be a great calamity if owners and occupiers of farms did not at once begin to provide better shelter and purer water for their cattle. The impure water which many had to drink, and the sewage which they had to trample in, increased the virulence of foot-and-mouth disease. Swine-plague would spread more and the disease be more virulent where the animals were kept in a filthy state. Many medical men were of opinion that tuberculosis was transmitted from animals to man. Tuberculous diseases and diseases of the mouth and throat were, as a fact, increasing, and it was certain that man was more secure from disease when living on sound food than on that which was unsound or diseased. The drinking-water for a large number of the cattle and sheep in England was now polluted with sewage. The housing of cattle was also of great importance. He had the authority of several practical butchers for stating that formerly very few cows in England were found with diseased lungs and liver, and that now very few cows of five or six years were free from disease of the liver or lungs, or some part of the body. This, in his opinion, was due to there being insufficient shelter from heat and cold, together with an insufficient supply of pure water.

After a vote of thanks to the President, the Section then adjourned.

## INTERNATIONAL CONGRESS OF DERMATOLOGY AND SYPHILOGRAPHY.

*Held in Paris, France, August* 5, 6, 7, 8, 9, *and* 10, 1889.

(Special Report for THE MEDICAL RECORD.)

DR. RICORD, Honorary President, formally opened the Congress in a few well-chosen words, and others followed with addresses of welcome, after which the scientific work was begun. There were six subjects announced for discussion, to each of which it was determined that the forenoon of one day would be devoted, the afternoons being occupied in the reading and discussion of voluntary communications.

### DISCUSSION ON LICHEN.

DR. KAPOSI, of Vienna, said that the term lichen was formerly used to denote any eruption of small papules, and Hebra was the first to limit its application to a special pathological condition, of which he recognized two forms, called, respectively, lichen ruber and lichen scrofulosorum. In 1877 the speaker pointed out that there were varieties of lichen ruber, viz., lichen ruber planus of Wilson, and the lichen of Hebra, which he had ventured to call lichen acuminatus. These two forms may coexist in the same person, but the latter may be found alone. It is always fatal. The two forms, although apparently different, are yet identical. The existence of lichen acuminatus has been denied, but without justice. The disease does exist, although it is very rare, and it should not be confounded with the affection which the Americans, and with them Unna, call by the same name, nor with the pityriasis rubra of Hebra. Whether it was identical with the pityriasis rubra pilaris of Devergie, the speaker confessed himself unable to decide.

DR. JAMIESON, of Edinburgh, believed that lichen was a disease, *sui generis*, and he accepted the classification of Kaposi. He did not think that Kaposi's lichen acuminatus was identical with Devergie's pityriasis rubra pilaris. The difference was plainly marked by the results of treatment, for arsenic is of considerable efficacy in lichen but useless in the pityriasis of Devergie. The latter affection is accompanied by pityriasis capitis, which is not met with in the lichen acuminatus of Hebra.

DR. HALLOPEAU, of Paris, thought a mistake had been made in grouping several distinct affections under the common designation lichen, which were related to each other only in general appearance. The only disease to which the term should be applied was the

### LICHEN RUBER OF WILSON.

The speaker distinguished an acute and a chronic form, and divided the latter into several varieties, such as planus, acuminatus, obtusus, tuberosus, etc. A certain number of cases reported as lichen ruber acuminatus belonged really to the acute form of this disease. He did not believe in the existence of a lichen scrofulosorum, but regarded the affection called by that name as nothing but a seborrhœa occurring in a scrofulous individual.

DR. HANS HEBRA, of Vienna, denied the identity of Devergie's pityriasis rubra pilaris and the lichen acuminatus of Hebra. The latter, he claimed, was a distinct disease, affecting the general system, accompanied by albuminuria, and terminating in death, while the former was a much less serious affair. Anatomically, also, the two affections differed. The

### LESION OF LICHEN ACUMINATUS

took its origin in the derma and extended toward the surface, but that of pityriasis pilaris travelled from the epidermis to the derma. In the former disease there are also lesions on the mucous membranes which are not present in the other affection. Finally, a characteristic feature of lichen acuminatus is the rapidity of its spread, involving, as it does sometimes, the entire body within a month, or even less time.

DR. BOECK, of Christiania, agreed with the previous speakers in believing these two affections to be distinct, and said that their non-identity was clearly shown by the appearance and characters of the lesions.

DR. UNNA, of Hamburg, also regarded the two affections as distinct, but there was some confusion in the minds of the speakers which he wished to remove. The affection described by Kaposi as lichen ruber acuminatus was by no means the same as that of Hebra. The latter is a trophoneurosis, and he would prefer to call it neurotic lichen. Kaposi's affection was the same, in his opinion, as that described by Devergie.

DR. SCHWIMMER, of Buda-Pesth, said there were two forms of lichen acuminatus, one mild (Wilson's), and one severe (Hebra's). Unna's assertion that lichen ruber acuminatus was a trophoneurosis was a pure assumption.

DR. LELOIR, of Lille, questioned whether it would not be better, as had been proposed by Hardy, to do away entirely with the lichen group, since the affections to which this term was applied differed so widely from each other.

DR. BESNIER, of Paris, thought the term lichen ought to be retained, and to be applied to the affection described by Wilson as lichen planus. It seemed to have been clearly shown by the discussion that the

### PITYRIASIS RUBRA PILARIS

of Devergie was distinct from lichen acuminatus; hence dermatologists should recognize the distinction in future. Under lichen he would recognize two forms—planus and acuminatus—and the latter might be again subdivided into several varieties. He could not accept Hebra's form, and believed that it had been confused with some other disease, for there was no practitioner living who had seen fourteen fatal cases of true lichen. The disease called lichen ruber by the Americans was the pityriasis ruber pilosa of the French. He thought further researches were necessary before it would be possible to determine the proper place of Unna's lichen acuminatus. Lichen scrofulosorum, so called, was not lichen at all, but was an acne, or some other form of skin disease occurring in a scrofulous individual.

DR. NEUMANN, of Vienna, demurred to this last statement, and maintained the existence of lichen scrofulosorum.

DR. DE AMICIS, of Naples, was a believer in the neuropathic nature of lichen.

Dr. Kaposi maintained that lichen scrofulosorum was a distinct disease. He also protested against the proposal to dismiss Hebra's lichen, for he regarded it as a type by itself.

Dr. Vidal, of Paris, advocated a wider use of the term lichen, and would have it embrace all papular affections, such as Wilson's lichen simplex, prurigo, strophulus, etc.

DISCUSSION ON PITYRIASIS RUBRA.

Dr. Pétrini, of Bucharest, in opening the discussion, said that he regarded primary, generalized exfoliating dermatitis, desquamative scarlatiniform erythema, and Hebra's pityriasis rubra as distinct affections. He had observed a case of the last named disease for a period of eight years, during all which time the character of the eruption did not change in the slightest degree. The cause of the furfuraceous desquamation, falling of the hair, etc., was to be found in the lesions of the arterioles, even producing obliteration of the vessels. The disease known as scarlatiniform erythema was quite rare. There was never any danger of confounding this with a drug eruption, for the latter never relapsed, unless upon renewed administration of the medicament. Exfoliative dermatitis is susceptible of cure, although this usually requires some time; it should not be mistaken for the acute form of Hebra's pityriasis rubra.

Dr. Brocq, of Paris, said that there were many affections of the skin characterized by a generalized redness, and more or less abundant desquamation. These have been described under various names, but for the most part under that of pityriasis rubra. Besnier has called them

ÉRYTHRODERMIES EXFOLIANTES.

These affections may be arranged under three heads with several subdivisions. In the first group are (1) pityriasis rubra pilaris (of Devergie), (2) pernicious lymphoderma (of Kaposi), and (3) the generalized red and desquamative eruptions of artificial origin. In the second group are, (1) the acute and generalized eruptions which occur not infrequently in the course of an eczema, of a psoriasis, or of a lichen planus, (2) Bazin's "herpétides exfoliatives." After all these have been disposed of there still remains a group to which the generic name of pityriasis rubra may be applied. This group comprises (1) desquamative scarlatiniform erythema, (2) exfoliative dermatitis, (3) chronic dermatitis, (4) chronic pityriasis rubra (of Hebra), and (5) subacute benign pityriasis rubra.

Dr. Crocker, of London, reported in full an interesting case of supposed pityriasis rubra, and gave a summary of twenty cases of the same affection.

Dr. Jamieson, of Edinburgh, said that pityriasis rubra of Hebra was but a stage of

GENERALIZED EXFOLIATIVE DERMATITIS.

This affection, which was often secondary to a pemphigus, eczema, lichen, or psoriasis, presented itself in two forms —one with small scales, the dry, and the other with large scales, the moist. He was not yet ready to express any decided opinion as to the relation between exfoliative dermatitis and scarlatiniform erythema.

Dr. Unna, of Hamburg, said that cases often had the appearance first of a psoriasis, and then later assumed that of Hebra's pityriasis rubra. Seborrhœic eczema might also terminate in the same way. If the disease were seen now for the first time, it might easily be taken for Hebra's pityriasis rubra. There is an intense, uniform, deep-red color with marked desquamation, and accompanied by a sensation of burning. The patient has repeated slight chills, loses strength and flesh, and finally dies. He thought that this secondary pityriasis was related to the pityriasis of Hebra, for both of them presented a characteristic sebaceous odor. Recurring desquamative erythema was, he held, merely a form of toxic dermatitis.

Dr. Schwimmer, of Buda-Pesth, said there were

TOO MANY DISEASES GROUPED UNDER THE NAME OF PITYRIASIS RUBRA.

Everyone knew that an eczema might take on the characters of dermatitis exfoliativa, but this was not pityriasis rubra as defined by Hebra. This term ought to be reserved for a specific affection, and should not be applied indiscriminately to every eczema or psoriasis which might assume a resemblance to it.

Dr. Vidal, of Paris, related a case which began as a seborrhœa of the scalp, face, and chest. The eruption, at first discrete, became gradually generalized, and had the peculiar sebaceous odor to which Unna had just referred. It then became scaly, the desquamative area increased in extent, an abundant sero-purulent secretion became established, and the patient finally died.

Dr. Kaposi, of Vienna, said that many diseases might resemble at times the one under consideration, but they were not it. One must have had a very large experience in dermatology to have convinced himself from personal observation that such a disease exists, and to be able to recognize it as a specific entity. In the first place, the disease is of rare occurrence, and in the second place, the diagnostic points are not easily distinguished. There are many forms of dermatitis, following an eczema or a psoriasis, associated with uterine or renal disease, caused by poisons or drugs, and the like, which may resemble this disease. In the true pityriasis rubra of Hebra the desquamation is fine, the skin preserves its suppleness, the redness and burning are present from the first and persist throughout, and the patient finally dies. If the patient recovered, that fact alone was sufficient to establish the incorrectness of the diagnosis.

Dr. Besnier, of Paris, in concluding the discussion, said that it was now established that there was but one form of pityriasis rubra, and that was the one which Hebra had described—a disease clearly distinct from the various forms of secondary exfoliating dermatitis. He wished, he said, to settle the question as to priority, which had been raised by certain dermatologists. It had been claimed that Devergie had preceded Hebra in his description of pityriasis rubra; but this was incorrect, for Devergie had evidently never seen the disease which Hebra called by that name.

DISCUSSION ON PEMPHIGUS AND THE COMPLEX OR MULTIFORM BULLOUS DERMATOSES.

Dr. Neumann, of Vienna, called attention to a variety of pemphigus which he had been the first to describe, and to which he had given the name pemphigus vegetans. At the onset of this disease the bullæ are of the size of lentils. These rupture, and from their site arise whitish elevations, which assume an irregular warty appearance, and become surrounded by a zone of minute bullæ. These excoriated surfaces secrete a foul-smelling fluid, and become covered with crusts. All parts of the body, even the mucous membranes, may be the seat of this eruption. When the buccal cavity is affected, the tongue becomes swollen, fissures occur in the mucous membrane, and the patient's sufferings are intense. After the acute stage is past, the tendency to verrucous growths diminishes, the skin becomes pigmented, and exfoliates in large sheets. The prognosis is grave. As to treatment, the continuous bath gives the best results. The diagnosis between this affection and syphilis is often difficult.

Dr. Crocker, of London, said that the description given by the last speaker fitted exactly a case recently under his own care. Hutchinson had reported some cases which seemed to be of this nature, and Duhring had also described a disease, under the name dermatitis herpetiformis, which he thought was the same as that of Neumann.

Dr. Brocq, of Paris, said that authors usually grouped all the various forms of multiform bullous dermatoses with pemphigus; but among these was one with character-

istics sufficiently pronounced to separate it from the rest and to warrant one in regarding it as a distinct morbid entity. This was the

DERMATITIS HERPETIFORMIS OF DUHRING.

It had four cardinal features which were met with in every case. These were: 1. Polymorphism of the lesions (erythema, vesicles, bullæ, etc.). 2. Painful phenomena (smarting, burning, itching). 3. Chronicity, the eruptions appearing in successive crops. 4. The good general condition of the patient, notwithstanding the intensity of the local lesions. Alongside of this affection, however, is a class of painful polymorphous dermatoses which resemble it in some points and differ from it in others. The speaker had made an attempt to classify these forms of dermatitis under four heads, viz., chronic, subacute, acute, and relapsing of pregnancy. In the chronic form the lesions were polymorphous and appeared in successive crops, their appearance often varying at different periods in the same individual. The subacute form permitted of two subdivisions, one characterized by successive attacks separated by intervals of complete rest, and the other occurring as a single attack made up of successive crops, almost always overlapping each other, and extending over a period of from twelve to eighteen months. In the typical form of this variety the lesions are polymorphous, but cases are occasionally observed in which there is but one kind of lesion, papulo-vesicles, papulo-pustules, or minute bullæ. In the acute form there may be but one attack, or several successive ones, but their intensity and duration are such as to warrant the designation of acute. The fourth form was the polymorphous painful relapsing dermatitis of pregnancy, or herpes gestationis. As its name indicated, it occurred only in pregnant women, either during the course of gestation or in the week immediately succeeding delivery. The speaker believed that this classification would be found useful in helping to bring some order out of the confusion that now existed in respect to this class of lesions.

DR. SCHWIMMER, of Budapest, said that the disease to which Duhring had given the name of dermatitis herpetiformis had formerly been known under various names, such as vesicular erythema, bullous erythema, hydroa, herpes iris, etc. He proposed to retain the names for those affections, such as bullous or vesicular erythema, which had already been well described, and to reserve the designation dermatitis herpetiformis for that disease which was characterized by successive crops of a generalized vesiculo-bullous, pruriginous lesion.

DR. BROCQ then read a letter from Dr. Duhring, who was detained by illness from being present, in which he described succinctly the four cardinal characteristics of the disease under question as follows: 1, Marked polymorphism of the eruption; 2, constant painful phenomena; 3, long duration of the eruption, varying from several months to ten or twenty years or more; 4, good general condition of the patient despite the intensity of the cutaneous eruption.

DR. KAPOSI denied that the affection described by Duhring was a disease *sui generis*. Duhring himself, he said, had taken away impetigo herpetiformis, which he had first included under dermatitis herpetiformis, after Brocq had pointed out that it was a distinct affection. In like manner, he believed, the other diseases thus bunched together would come to be recognized as separate entities, according as our methods of diagnosis were elaborated. He had examined the case which had been exhibited by Brocq as an example of the affection, and which had also been examined by Duhring a short time before, and he saw in it the symptoms of ordinary pemphigus—nothing more. The lesions of pemphigus were of a varied nature, and he saw no reason for making a further distinction and setting forth a new and distinct disease.

DR. UNNA agreed with Brocq, and believed that there did exist a disease of a distinct clinical type characterized by the four groups of symptoms just related, and which was the dermatitis herpetiformis of Duhring. But since

THIS AFFECTION INCLUDES ALL THE FORMS OF HYDROA

(simple, subacute, grave, hereditary, and of pregnancy), it might just as well be designated hydroa.

DR. SCHWIMMER thought Kaposi was wrong in trying to force all the bullous affections into the single group of pemphigus. Confusion reigned here, and it was necessary to infuse some order into this class of diseases.

DR. BROCQ, in summing up the argument in favor of the existence of Duhring's dermatitis, said that there certainly was a disease characterized by the four groups of symptoms which he had detailed, and it ought not to be confounded with pemphigus, nor with a number of other bullous affections. What name was given to this syndrome of symptoms was of minor importance; let it be called dermatitis herpetiformis after Duhring, or hydroa after Unna, the fact remained that it was a distinct disease. He himself preferred the designation, as being more descriptive, though rather long, of chronic, pruriginous, polymorphous dermatitis.

## THE ETIOLOGY OF RICKETS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: A letter from Dr. Robert Lee, of London, was published in a March number of THE MEDICAL RECORD. Dr. Lee states that he has the impression that rickets is a rare disease in the United States, and expresses a wish to learn the ideas of American physicians regarding the etiology of rickets. He is of the opinion that rickets is produced by any disease in infancy which interferes with respiration. In a late issue of THE MEDICAL RECORD another letter appears from the same gentleman, in which he expresses regret that there is a tendency (as shown by a paper upon rickets, by Dr. Irving M. Snow) to explain the views of others, and not to give the results of personal observation. He also denies that there is evidence to show that want of proper food is a cause of rickets, as it is common among the children of the wealthy classes of English society, whom he evidently supposes are properly nourished.

My paper upon rickets, read before the alumni of the Buffalo Medical College, was not written in answer to Dr. Lee's letter. Its object was to awaken the attention of physicians to the frequency of rickets in America. Thus I reported twenty-five cases found among fifty-eight children under three years, from asylum and dispensary service. I stated my belief that rickets is commonly due to unsuitable diet, chiefly to a deficiency in fat. Every physician knows that the correct proportion of fat is lacking in artificial farinaceous food, or in diluted cow's milk. Most rachitic children are hand-fed, or, if suckled, receive in addition some farinaceous food. These views of the causation of rickets are those of Dr. Cheadle, of London, a physician to the great Ormond Street Hospital for Sick Children, London. I endeavored to show that rickety children were excessively liable to pulmonary diseases and to disorders of the gastro-intestinal tracts, and that a bronchitis or an entero-colitis might often be regarded as an intercurrent malady in a rachitic child.

Many continental and English authorities were cited, who held that, with children dead of respiratory and diarrhœal diseases, the enfeebled muscular power and disordered digestive functions of rachitis were often the direct cause of the fatal issue.

Now, as rickets is not commonly recognized in its early stages in this country, the subject was treated at great length, and I thought best to quote from the writings of many eminent men. All of this Dr. Lee criticises, think-

ing the profession are sufficiently enlightened as to its symptomatology, and evidently wishing that American physicians may be able to prove that the precedent cause of rickets is in disordered respiratory organs.

Of 13 rickety children examined by me in orphan asylums, only 2 had ever suffered from any pulmonary disease. All of these were children who, at the time of examination, were under no medical care, but were feeble and backward in development. Among 11 cases of rickets seen at the Fitch Dispensary, in 6 there was no history or present symptom of bronchitis or other pulmonary disorder, while 5 either had suffered or were afflicted with bronchitis or pertussis. Another well-marked case of rickets in an infant aged eight months showed no history of bronchitis. It was suckled, and was also fed upon crackers (biscuit) soaked in cow's milk. The child suffered from colic and dyspepsia.

The farinaceous food was withdrawn, and a teaspoonful of cream given three times a day. The excessive sweating ceased, two teeth appeared in three weeks, and the child grew strong and active.

Thus I am unable to assist Dr. Lee in proving his theory, that bronchitis, pneumonia, etc., usually precede the development of rickets, and are to be regarded as the precedent cause. Every experienced physician must concede that a previously healthy child will often become rickety during the course of bronchitis or whooping-cough, yet there are many rachitic children who have never suffered from cough or bronchitis.

Dr. Lee's letter is most courteously worded, and if he succeeds in awakening in the United States an interest, either in the frequency or etiology of rickets, he will do the profession a lasting service.

IRVING M. SNOW, M.D.

371 PORTER AVENUE, BUFFALO.

## "THE PHYSICIAN SHOULD BE EITHER A CHRISTIAN OR A PHILOSOPHER."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: When I read THE RECORD'S creed, "The physician should be either a Christian or a philosopher," I embraced it with devotion, and have, since then, chiefly looked to it for my medical gospel. And when, after your late editorial "On Continence and Syphilis," the *bizarre* announcements of Brown-Séquard were sprung upon an astonished world, I patiently awaited the usual virile criticisms of THE RECORD to purify and thoroughly sift these dogmas, which seemed the emanations of an intellect once great, but now in its decline.

But even Homer sometimes nods. It is presumed that no one will call these views "Christian;" as for being philosophic, let us take the statement of Brown-Séquard himself:

"It is known that well-organized men, especially from twenty to thirty-five years of age, who remain absolutely free from sexual intercourse, or any other causes of expenditure of seminal fluid, are in a state of excitement, giving them a great, though abnormal, physical and mental activity."

Now, if we accept this simple statement without regarding the word "abnormal" as *sub judice*—which, in the light of the teachings of Carpenter, the physiologist, Dr. S. D. Gross, Dr. William R. Gowers, Sir J. Paget, etc., we might fairly do—what father would not prefer for his son the supposed dangers of "abnormal physical and mental activity" to syphilis, gonorrhœa, spermatorrhœa, and—worst of all—an unscathed career of sensuality?

Brown-Séquard's teachings ignore the duty and necessity of self-restraint—at least they will be generally so interpreted—and hence, coming from one who speaks with authority, they are capable of doing great harm.

"Corruptio optimi pessima."

The involuntary surroundings of vast numbers of men for life, and of every man at certain periods, are such that nothing but continence can prevent loss of self-respect and the esteem of our fellow-men.

The fatal dogma that sexual intercourse is essential to health, and that an involuntary emission from the sexual organs, when within physiological limits, is noxious, is the chief capital of the hordes of medical vampires, and has ruined, and is still ruining, untold numbers of young men.

True, it is hard for a man who is a "good animal" to always control his sexual appetite; it seems no less true that no man is safe, either as to his own welfare or that of those who are near and dear to him until, by the aid of philosophy and religion, he has learned to climb up from his mere animal nature and take refuge from the illegitimate demands of passion in his moral and intellectual being.

Carpenter says: "It is a general law, which pertains alike to the vegetable and animal kingdoms, that the development of the individual and the reproduction of the species stand in an inverse ratio to each other."

To the legitimate application of the new treatment no one should object; but against encouraging mere sensualism, from which the world now chiefly suffers, I think every honorable physician should raise his voice and wield his pen.

Young men should be guided by the counsels of Carpenter, to keep their minds and bodies usefully employed, and they will think much less about their sexual organs; and let them not be alarmed if an involuntary emission occurs once in twelve or fourteen days, which seems just as physiological, and no more injurious, than the analogous flow from the female organs. These words are trite, but are necessary. It is every man's duty to learn this great lesson—to make obedient the beast within him—and, having learned it, to teach it to others; once thoroughly learned, "the yoke is easy and the burden is light."

Respectfully yours,

W. F. M.

[We have already expressed positive opinions on these points, agreeing with our correspondent.—ED.]

## GASEOUS ENEMATA FOR INTESTINAL OBSTRUCTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of August 3d I see an article from Dr. Dewitt C. Rodenhurst, reporting "a case of intestinal obstruction" relieved by the use of gaseous enema. If you will refer to page 155, August 6, 1887, of THE RECORD, you will see a case reported by myself, in which I relieved a patient in the same way. Perhaps it is well enough to call your attention to that portion of Dr. Rodenhurst's article where he speaks of the method as introduced by Dr. Senn, of Milwaukee, Wis. I do not recollect having seen anywhere that Dr. Senn used the treatment for removal of obstructions of intestine, though I have within the past year seen where he used it for diagnosing intestinal perforations. Since I first used the method I have had occasion several times to use it again for intussusception of bowel and fecal obstruction, and have found it a valuable remedy, but not by any means invariably successful. There are several precautions to be used in administering the gas, such as care in not overdistending the bowel, and carefulness in using the best chemicals, and not to inject air instead of the gas, as I had the misfortune to do once, by omitting to turn the stopcock attached to the gas-bag.

In corresponding with you after my report of the case in August, 1887, you wrote, in speaking of the method, that it was as "old as the hills," which, in connection with the recent reports of Dr. Brown-Séquard's "Elixir of Youth," leads me to exclaim that "there is nothing new under the sun," for on the farms and plantations where sheep, hogs, and cattle were raised, the custom was at stated times to castrate the male animals, and many times

I have seen the negroes and other employees broil the excised testes on the fire-coals in the lots where the animals were kept, and partake of same with much relish and with many a jest as to its stimulating effect on the functions, particularly of the generative organs, and also as to its increasing their strength to split rails and lift the cotton-baskets. The primitive mode of cooking the dish was due to a delicacy in asking the female cooks to prepare food fit only for the "lords of creation."

Respectfully yours,

W. P. COPELAND, M.D.

EUFAULA, ALA.

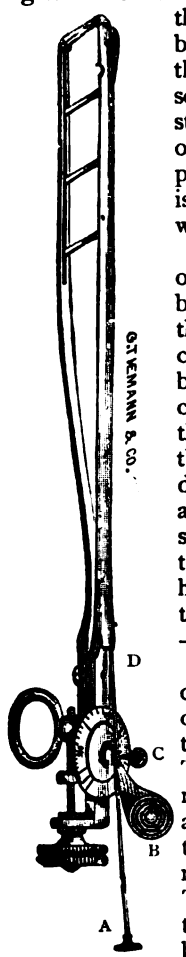
## New Instruments.

### AN IMPROVED URETHROTOME.

BY J. D. THOMAS, M.D.,

PROFESSOR OF GENITO-URINARY AND VENEREAL DISEASES, WESTERN PENNSYLVANIA MEDICAL COLLEGE, PITTSBURG.

ALTHOUGH the Otis urethrotome is recognized as possibly the best instrument presented to the profession for severing strictures of large calibre, it has, in my experience, three faults: First, that after the knife or blade is drawn forward and made to cut the stricture, it has to be pushed back; second, it must be readjusted for each stricture after the first is cut; and, third, owing to the fact that it opens on the principle of a parallel ruler, the adjustment is slightly altered after it is opened from what it was when first set for the stricture.



The first objection is the most serious one. Although it is intended, when the blade is pushed back, that it shall traverse the same line as was made by the forward cut, in practice it does not do so, but goes back along a *new* line; for the loose character of the tissues of the penis makes this unintentional cut unavoidable, and, as the distal end of the blade is somewhat dull, it makes in addition the cut a lacerated one. The second objection is not such a serious one, but the readjustment takes time and necessitates needless and hence injurious manipulation of the urethra. The third objection is a trivial one—but an objection, notwithstanding.

With my improvement, which is here displayed, these objections are all overcome. The rod A slides to and fro in the slot in the upper bar of the instrument. The blade B is slid forward on top of this rod, and when the instrument is closed and ready for introduction into the urethra, the blade is beyond the end of the rod, down in the slot, and out of the way. The urethrotome is then introduced to the bottom of the penile urethra—to the bulb—and opened, regardless of the location of the stricture or strictures. The seat of strictures having been previously located, the rod A is drawn forward until its extremity is at the point of deepest stricture, and fastened in place with the screw C; then the blade B is drawn forward, and when it arrives at the extremity of the rod A it rides up on this and cuts the stricture. The rod is now released and drawn forward to the seat of the next stricture, and again fixed with the thumb screw C. When the rod is drawn forward the blade always drops into the slot and is out of the way, so that it can be drawn forward, and when it arrives at the rod it rides up on it and cuts the next stricture. When there are more than two strictures the same process is gone through with until all strictures are cut—always cutting the deepest first.

It is not necessary to have any markings on the rod to indicate where the strictures are, for they can be located for the blade by deducting the distance from the meatus to the strictures from the length of the rod; *e.g.*, if a stricture is at five inches, the rod being eleven inches, six inches of the rod is left outside of the meatus, and when the blade is drawn forward it rises exactly where we want it to—at five inches.

The improved instrument has another advantage over the original Otis—when the blade and rod are removed it is easier cleaned.

When introducing the rod or blade into the instrument, if the thumb is placed at the point D, and a little pressure made, we utilize a knack that will facilitate materially the ease with which they slide in.

Having had some experience with the instrument, I find it works admirably.

To know that the blade has dropped into the slot it is only necessary to draw the proximal end of the rod one inch beyond the same end of the knife.

## Army News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 25 to August 31, 1889.*

TREMAINE, WILLIAM S., Major and Surgeon, now on sick leave of absence at Buffalo, N. Y., by direction of the acting Secretary of War will report in person to the commanding general of the Department of the Missouri for assignment to temporary duty at the post of Fort Leavenworth, Kan. Par 4, S. O. 198, A. G. O., August 20, 1889.

PORTER, JOSEPH Y., Captain and Assistant Surgeon. Resignation has been accepted by the President, to take effect, August 29, 1889. Par. 11, S. O. 200, Headquarters of the Army, A. G. O., August 29, 1889.

MATTHEWS, WASHINGTON, Captain and Assistant Surgeon. Promoted to be Surgeon with rank of Major, July 10, 1889, *vice* Town, promoted.

EWING, CHARLES B., Assistant Surgeon. July 5, 1889, promoted to be Assistant Surgeon with rank of Captain, after five years' service, in accordance with act of June 23, 1874.

MCCAW, WALTER D., Assistant Surgeon. August 20, 1889, promoted to be Assistant Surgeon with rank of Captain, after five years' service, in accordance with act of June 23, 1874.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 31, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 106 | 16 |
| Scarlet fever | 16 | 1 |
| Cerebro-spinal meningitis | 2 | 2 |
| Measles | 23 | 1 |
| Diphtheria | 80 | 23 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

RECENT STUDIES OF TWO HEART TONICS.—A series of experimental studies upon the physiological action of strophanthin has been recently made by Dr. Jacques Popper, of Vienna; certain clinical observations upon the therapeutic value of spartein have been made by

Dr. S. W. Lewaschen. The papers of both these gentlemen have recently appeared in the *Zeitschrift für klinische Medicin*, Bd. xvi., Hft. 1 and 2. Dr. Popper's first series of experiments was made in order to determine the influence of strophanthin upon arterial pressure. They resulted in showing a very constant and persistent increase of this tension. This rapidly reached its maximum and then gradually diminished, though it did not fall to normal. The pulse was at the same time slowed. Another series of experiments was made upon the blood-pressure in the veins, with most interesting results. They showed that the venous pressure became slightly diminished as a rule, while that of the arteries was increased. This phenomenon is explained by the fact that the smaller arteries are contracted and tense, shutting off some of the flow of blood into the capillaries and veins, while the larger arteries are dilated, tense, and full. The conditions are thus united to a rapid emptying of the veins into the heart. Experiments made to test the influence of strophanthin upon the pressure in the aorta and pulmonary artery showed that while the pressure in the former was increased that in the latter was either diminished or very little affected. The total result was to change the relations of the pressure in the aorta to that in the pulmonary artery from the normal of 5.9 to 1, to that of 8 to 1. Thus it is shown that strophanthin increases the tonus of the arterial system, but lessens absolutely or relatively that in the systemic veins and in the pulmonary circulation. A series of experiments were made in order to determine whether the increase of the blood-pressure was due to a stimulation of the vaso-constrictor nerves and contraction of the arterial walls. The observations showed that strophanthin does not act in this way, but rather that it causes increased blood-pressure mainly by over-distending the arteries. The action of strophanthin in slowing the heart-beat was shown to be in part at least due to stimulation of the vagus inhibitory apparatus. A clinical study of the action of spartein upon the circulatory apparatus is of more practical interest. Dr. S. W. Lewaschen, as the result of his experiments, comes to the following conclusions: Sulphate of spartein strengthens and regulates the heart-beat and slows it if it is too rapid. This action is accompanied with increase of blood-pressure, increased flow of urine, relief of œdema and dyspnœa. The diuretic action of spartein is only an indirect one, it has no specific action on the renal epithelium. Spartein is a less powerful heart tonic than digitalis, adonis, or strophanthus. This is shown by the fact that in very severe forms of cardiac degeneration and weakness spartein will not act, while the other drugs do. The tonic action of spartein, however, may last for several days after its use has been suspended. If spartein acts at all it acts rapidly, often within fifteen minutes after its administration. The rapidity of its action makes spartein a useful drug in cases of sudden heart failure where the organ is not seriously diseased, as, for example, in the acute fevers. The dose is from two to five grains daily.

Short-hand in Medical Study and Work.—A number of London physicians have started a movement for the encouragement of the study of short-hand by medical students or those professing to study medicine. A series of examinations are to be held in October, and prizes offered. A memorandum published in connection with this movement says: "The physician is aided in a special manner by the fulness of the notes of cases that can be taken. To him, in his effort to advance our knowledge of medicine, and to all who cultivate the sciences that rest on observation, short-hand is of peculiar value by increasing, at least threefold, the amount of recorded observation, recorded while the phenomena are in progress. The value of this increase, in fact, is scarcely to be measured. Short-hand must lessen the influence of imagination in science, by increasing the amount of influence of definite fact. In the observation of disease especially, in which so much has frequently to be recorded in a short time, the effect of its general use would soon be perceptible in the greater exactness and minuteness of our knowledge. Its influence extends, in the same manner, to the processes of comparison and collation of facts, and, indeed, to almost all the processes of work, up to actual composition for the press." Uniformity in the system of short-hand is thought most desirable, and Pitman's system is recommended as being the one used by ninty-five per cent. of short-hand writers. We have occasionally referred to the subject of the advisability of learning short-hand, and have uniformly discouraged any introduction of the practice. To learn it so that it will be really useful requires a great deal of time which might be better spent. The opportunities for its use after entering practice are not frequent. Long-hand notes answer every purpose of case-taking. If a person has a special taste and aptitude for it, however, or if he plans to use it in reporting or journalistic work, the case is different. We would add that in this country, so far as we know, Munson's system is nearly as popular as Pitman's, of which it is, however, only a modification.

Potatoes as a Substitute for Laparotomy.—At a meeting of the Imperial Society of Physicians in Vienna, Dr. Salzer reported a communication from Dr. Cameron, of Glasgow, upon the "potato cure" first recommended by the Scotch observer. Dr. Cameron has used this plan of treatment in several cases of ingestion of large foreign bodies with gratifying success. Salzer has also had an opportunity to try the potato cure in the case of a boy who had swallowed a brass weight of twenty grammes. Potatoes were fed to the child, cooked in a variety of manners, so as to encourage his appetite. He took them willingly. After five days the brass weight was compelled to retreat, overwhelmed by the constant accessions of reenforcements from above, and passed out, leaving the potatoes in possession of the field. In the same manner he treated the ingestion of a set of artificial teeth, while in another case a scarf-pin proved no match for its farinaceous antagonist. Dr. Salzer believes that this form of treatment will subserve a useful purpose in many cases in which, up to now, gastrotomy appeared to be the only form of relief available. He also advised the members to place no trust in sauer-kraut, which has been recommended for the same purpose. Dr. Hochenegg related the case of a boy who had swallowed a nail 6 ctm. long, in 1884, and had been treated by gastrotomy. He had swallowed a similar nail two years later, when the potato cure had proved successful. Dr. Billroth spoke of the difficulty which exists in the removal of foreign bodies by laparotomy, and was strongly in favor of the potato cure. —*International Journal of Surgery.*

A Substitute for Ichthyol is said to have been found in thiol, a synthetically formed substance (*Notes on New Remedies*). The latter is prepared in two forms, liquid thiol, a forty per cent. solution, and dried thiol, obtained by carefully evaporating liquid thiol. Its odor is slightly bituminous, and its taste bitter and astringent. Like most of the new remedies produced in Germany, it is a patented preparation.

Hard to Please.—*Indignant Physician:* Man, what have you done? You sent my patient the wrong prescription, and it killed him. *Druggist* (a calm man, accustomed to abuse): Vell, vhat vas der madder mit you? Last veek I send your odder patient der righd berscription, and dot killed him. How can somebody blease sooch a man?

A Strange Industry.—Two companies exist in one of the German cities, whose special business it is to manufacture machinery and all the appurtenances for making artificial unground coffee—pure Java in the berry. A roasted meal of some kind, made cohesive with dextrine and pressed in moulds, and afterward polished, is how it is done. The artificial coffee is said to be a very good imitation, and when mixed with the real article is not easily picked out as false.—*The Sanitary Inspector.*

### CHOLECYSTOTOMY.[1]

BY NEIL MACPHATTER, M.D.,

CLEVELAND, O.

THE operation of cholecystotomy is not a new one. Like many others it was described and anticipated by several of the old surgeons. In looking up its history I find that in the year 1618 it was performed by Johannes Fabricius, who removed several gall-stones from the gall-bladder. Later on Fabricius Haldiaus is thought to have performed it. But it was not until the time of that very clever surgeon, Petit, that the operation of cutting into the gall-bladder and removing gall-stones was first established upon anything like a scientific and surgical basis. I read that this excellent surgeon described the tumors of the gall-bladder, and the symptoms accompanying them, as well as the operative proceedings, with so much accuracy that his details could almost now be accepted. The ability of Petit was not, however, recognized at the time; but, upon the contrary, his teachings upon this subject met with almost universal condemnation. From this time until a few years ago little or no advancement was made, although several surgeons wrote upon the subject, among them being Sharp, Brimfield, Chopart, Morgagni, Haller, and others. Sebastian endeavored to establish an operation whereby the peritoneum and gall-bladder were made to become adherent before the incision into the gall-bladder was attempted. Thudichum secured the gall-bladder to the abdominal wound by sutures several days before cutting into it. Bobbs, of Indianapolis, closed the incision in the bladder by sewing it up and afterward suturing the abdominal incision. This was the condition of this operation when Lawson Tait took it up and established it upon a firm and satisfactory basis, having had fifty-two operations with but two deaths, one of which cannot properly be attributable to the operation itself, but rather to the extreme condition to which the patient was reduced at the time of operation.

The experiments made upon animals, and other investigations that have from time to time been carried out, fail to give us a proper idea of the function of the gall-bladder. We are as yet groping in profound ignorance on this point. The theory up to now advanced, that it is a store-room for bile, cannot longer be accepted. A more plausible one is that it secretes a mucous fluid which mingles with the bile as it passes down the duct and renders its passage more easy. Occasionally a small quantity of bile is found in the gall-bladder, but this does not take away from the argument. This may be accounted for by some temporary occlusion in the common duct which would cause the bile to flow backward through the cystic duct into the bladder.

For many years the profession have been investigating the origin and cause of gall-stones. The theory advanced many years ago by Dr. Thudichum, that they arise from deposits of cholesterin, which form about the minute ramifications of the smaller ducts, is the one now generally accepted. Whatever be their cause, gall-stones do not always form in the gall-bladder, as is almost universally believed, but in the liver substance itself. They there frequently give rise to suppuration and abscesses of large size. The samples which I now hand you in this bottle were taken out of the liver tissue. It was necessary to cut through the liver structure to the depth of over an inch before they could be reached. I believe they almost always have their origin in the liver, and pass down the hepatic and cystic ducts to the bladder, where they further develop and multiply. It is after they have accumulated in the gall-bladder, and there give rise to serious symptoms that the great bulk of cases attract attention and call for surgical relief. According to the theory and teachings of Lawson Tait there are two varieties of gall-stones. These two varieties differ in their history, symptoms, pathology, and treatment; they are the solitary variety, when usually not more than one or two stones of large size will be present, and the multiple variety, when a large number of small stones of almost uniform size will be found. Many hundreds are sometimes present, and from pressing and rubbing against one another their surfaces become faceted in a characteristic manner.

The large variety of stone has a distinct and characteristic history, and a different line of symptoms, as compared with the numerous kind. It is almost invariably of large size, and grows very much like a urinary calculus. It may remain for an indefinite length of time in the gall-bladder without giving rise to any symptoms whatever, or even suspicion of its being present there. It usually makes its presence known by suddenly becoming lodged in the beginning of the cystic duct. From that moment, by completely occluding the duct, the bile cannot enter the gall-bladder. The mucous fluid goes on developing until it completely fills the bladder. When the stone becomes lodged it cannot pass down the duct, owing to its large size. It therefore becomes impacted there, and may lead to ulceration and suppuration, and may liberate itself in one of the two following ways, either by setting up an adhesion with some part of the intestine and establishing a fistulous opening, or the fundus becoming attached to the abdominal parietes and suppurating in an outward direction. Many large stones have been known to pass out in this manner. While this stone is lodged in the duct the mucous secretion goes on increasing from day to day, and gradually distends the bladder until it is sometimes enlarged to an enormous extent. The operation, when this distention is present, is much easier than when the bladder is only of normal size, although a great difficulty may arise in removing the impacted stone. It may be necessary to chip it away in pieces, as I shall show when discussing the treatment. The distinct characteristic of this variety is the distention of the gall-bladder by means of mucous fluid; so great does this enlargement sometimes become as to make its diagnosis from other cystic tumors, especially cystic enlargement of the right kidney, difficult indeed.

Clinically the multiple variety differs in its symptoms and treatment from the solitary kind. Lawson Tait maintains that they differ also in their pathology. I do not care to have my opinion taken in preference to that of my distinguished teacher, as he seldom gives expression to an opinion without substantial grounds; yet I cannot help thinking that there is no difference pathologically between these two varieties. Whether my view on this subject be correct, the two varieties, to my mind, are but modifications of the same cause. It is well known, as I

[1] Read before the Ontario Medical Association, June 6, 1889.

have already stated, that gall-stones form in the liver tissue itself. As a small stone passes down the ducts into the bladder and there develops, the tendency is that its coats chip off into small fragments which act as the nuclei for others. In this way these stones may go on developing and forming until a very large number be present. Now, if from some cause or other the original or parent stone does not chip its coats or break up into fragments to form nuclei, but goes on individually developing, the solitary variety, with its peculiar characteristic symptoms, will be the result. An important matter that would seem to bear this argument out is that the nucleus of the multiple variety is altogether different from that of the solitary, which usually cannot be found. The gall-bladder is seldom or never much enlarged in cases where patients are suffering from multiple stones. The reason of this is that they are nearly all sufficiently small to pass down the cystic duct. Their uniformly small size is such as to facilitate this. They are not lodged long in the cystic, and on account of the common duct being shorter and wider, it consequently follows that a stone that can pass down the cystic will, with greater ease and speed, pass through the common duct. It is for this reason that we seldom find jaundice as an accompanying symptom of gall-stones. Jaundice can only take place while the stone is passing through the common duct, and as it is wider than the cystic the stone is not lodged in it sufficiently long to give rise to this symptom. The symptoms accompanying the presence of gall-stones are not constant, and may be quite irregular. A large stone or a number of small stones may be present, and yet give rise to no symptoms. Usually, however, there will be a history of the patient having had biliary colic, with its characteristic paroxysmal pains. The stones may set up inflammation and suppuration, or may become impacted or wedged in the cystic duct. They have been known to ulcerate through the bladder and set up fatal peritonitis. When the impaction takes place in the cystic duct the changes and symptoms will be of a local character. When the hepatic or common duct is obstructed there will be present symptoms of jaundice, and should this obstruction continue for any length of time, general cholæmia will set in and reduce the patient's chances in an operation very materially. Frequently an enlargement below the margin of the liver will be quite readily detected. The amount of enlargement that may be present varies from the size of your fist to a large cystic tumor, that may be mistaken for cystic enlargement of the right kidney. It has before now been mistaken for ovarian cyst. In all cases this enlargement will have its commencement in the region of the gall-bladder. Very frequently a rigid rectus muscle simulates the symptoms of commencing enlargement of a gall-bladder, and I would warn my readers to guard against this point.

I cannot agree with the statement of J. W. Taylor, that the line of enlargement is usually in a diagonal line from the fundus of the bladder to the umbilicus. I have never yet witnessed this, but have invariably found, when the enlargement is present, it is about two inches to the right of the umbilicus, and immediately below the normal situation of the bladder. The shape of this enlargement will be round or pyriform, and will give a dull note on percussion. In diagnosing, care is required to distinguish between cystic enlargement of the right kidney, hydatids, and malignant disease of the liver. The peculiar condition of a gall-bladder being quite distended one day, and upon examination a day or two following regaining its normal size, may be owing to temporary occlusion while a stone is passing through the cystic duct.

The operation for the relief of these conditions differs somewhat in some of the details. In the solitary variety, as I have already stated, the gall-bladder is usually distended, and the diagnosis is more certain. In the multiple variety the bladder will be of normal size, more difficult to find, and does not require to be emptied as the other. The usual preliminary precautions are as essential in the operation of cholecystotomy as in any other abdominal section. Therefore strict cleanliness of patient, instrument, and surroundings is absolutely called for. The patient is put in the ordinary position, as for ovariotomy, and the anæsthetic given. When the enlargement of the gall-bladder is so great as to be readily felt, the proper incision is that directly over the tumor, vertically downward. When no enlargement can be made out, the incision should begin over the situation of the fundus of the gall-bladder. This is found directly beneath the tip of the cartilage of the tenth rib. The various textures are now cut through rapidly, until the peritoneum is reached. If any hemorrhage be present, it is arrested by sponges or forceps. Layer after layer is next held up between two pair of forceps, and gently divided, until an opening into the peritoneum sufficient to admit the tip of one finger is made. An exploration is now instituted. If the gall-bladder is enlarged, and especially if cystic, little or no difficulty will be experienced in finding it. When it is of normal size it is sometimes difficult and almost impossible to find. The subsequent steps of the operation are much easier when the bladder is distended. Generally the finger comes in contact with it immediately beneath the opening. A curved trocar is now inserted and the fluid drawn off. By this means the bladder can be drawn out through the opening sufficiently far for the subsequent steps of the operation. With a small scalpel the opening into the bladder is made, beginning at the side of the trocar. A flat sponge is placed below and around the bladder, for the double purpose of keeping back the intestine and absorbing any fluid or bile that may chance to fall downward. The opening thus made is now held apart with forceps by an assistant, and it is absolutely necessary that the assistant should be competent to fulfil this most important and particular duty. Indeed, it is as essential here that the assistant should be familiar with his duties, and anticipate the wishes of the operator, as it is for the surgeon to know how to operate. Ill-judgment or undue haste may be the means of disastrous results.

With the scoop or alligator forceps the stones can be readily removed. When one is lodged in the cystic or common duct, the operation becomes prolonged and much more serious. This complication may call out the ingenuity of the surgeon to the utmost. If lodged in the beginning of the cystic duct, it may be necessary to chip it away in pieces. When in the common duct, Tait's plan of crushing it with muffled forceps may be tried.

When the stones are all removed the opening in the bladder is to be stitched to the abdominal incision. The sponge that has been left in the wound must first be removed, and everything around the incision made perfectly clean. Independent or continuous sutures may be used, according to the inclination of the operator. If the continuous method be adopted, one thread will be all that is necessary; the needle, threaded with No. 2 Chinese twist, being passed each time through cyst-wall, peritoneum, parietes, and skin. When the whole circuit of suturing is completed, the two ends of the thread are drawn tightly and tied together. The next step in the operation is the introduction of a rubber tube. Rubber is preferable to glass for this particular operation, as it better adapts itself to the respiratory movements of the parts. It should be fixed in position with a thread. The only dressing required is absorbent cotton wool, which may be changed as required. As soon as union between the wall of the gall-bladder and the abdominal incision has taken place, the stitches can be removed. The drainage-tube may be left in longer if required. Usually a biliary fistula is left, which generally heals up in the course of a few weeks. Occasionally the fistula continues, and may require an operation to permanently close it.

This operation is one of the many recent triumphs of surgery, and it is remarkable and gratifying to find patients who have been reduced to the lowest possible condition of health gain rapidly in condition in the course of a few weeks.

## NOTES ON EXALGINE.

By FREDERICK PETERSON, M.D.,

LECTURER ON NERVOUS AND MENTAL DISEASE AT THE NEW YORK POLYCLINIC.

At a meeting of the French Academy of Sciences, March 18, 1889, Drs. Dujardin-Beaumetz and G. Bardet presented a report upon the physiological and therapeutic action of orthomethylacetanilide (*Gazette des Hôpitaux*, April, 1889), a derivative of benzine, to which the name exalgine was given by Brigonet, the chemist who prepared it. It is very soluble in water containing a little alcohol, somewhat so in warm water, but only slightly in cold water. They found it to act very energetically upon the cerebro-spinal axis in animals, giving rise to phenomena of impulsion, tremor, and paralysis of the respiratory muscles. In non-toxic doses sensibility to pain disappeared, but that to touch persisted; and a gradual but notable fall of temperature took place. Compared to antipyrin, there is a considerable similarity, but the effect of exalgine upon sensibility is more marked, and upon the thermogenic centres less marked, than that of the former. In therapeutic use exalgine gave rise to no rash, cyanosis, or gastro-intestinal irritation, such as have been noted in the employment of antipyrin and acetanilide; in one case only was there slight erythema. They treated all forms of neuralgia with the new remedy, doses of twenty-five to forty centigrammes being required for the analgesic effects. The drug is eliminated by the urine. It modifies the urinary secretion, and in diabetic polyuria diminishes the daily amount of urine and the quantity of sugar. Compared to antipyrin it seems to produce greater effects as an analgesic in half the doses, according to these authors. It has also to some degree antiseptic properties.

I have been testing the efficacy of the drug on private patients, and on patients at the Polyclinic and Vanderbilt clinics, as appropriate cases presented themselves, during the last seven weeks. I have used it in the form of pills containing two grains each, and in the form of a cordial, each tablespoonful of which was equivalent to two and one-half grains of the drug (both forms prepared by McKesson & Robbins). Notes in some of the cases are here appended:

Case I.—A. S——, female, aged twenty-four, suffering from trigeminal neuralgia, upper two branches, and extending also over occipital region, several years' duration. It is proper to say that many remedies had been tried unavailingly. Two grains of exalgine was ordered every three hours. She took nine doses without any relief of pain, drowsiness, or apparently any effect. Aconitia and quinine prescribed since have also failed to secure relief.

Case II.—K. G——, female, aged nineteen, for a week or so had had cephalalgia, neuralgic in character, over the whole of the right side of the head. She could not sleep on account of the pain, and, as she expressed it, "was driven nearly crazy." There was good reason for suspecting the case to be malarial, and quinine was administered for some ten days, five grains three times daily, without, however, any effect. She was then ordered exalgine pills, āā gr. ij. every four hours. She took but four doses, and reported complete cure.

Case III.—A. W——, female, aged fifty, a paranoiac, troubled excessively by paræsthesiæ over the whole body, which gave rise to the delusion that electricity was being used upon her continually by her persecutors. Sleepless much of the time because of these shooting pains and prickling sensations. For two nights she took exalgine, one dose only of two grains each night, and slept soundly, the pains not recurring until morning

Case IV.—S. H. B——, male, aged fifty-two, supra-orbital neuralgia for three months. Pain much diminished by exalgine, gr. ij. every four to six hours.

Case V.—S. D——, female, aged thirty-six, occipital neuralgia for two months past, of probable malarial origin. Twenty grains of quinine daily for three days produced no effect. Exalgine was ordered in two-grain doses every four hours for several days. Patient stated that she felt a sort of drowsiness, but the pain was not diminished in the least.

Case VI.—J. D——, male, aged sixty, occipital and supra-orbital neuralgia of some weeks' duration. Was treated with quinine and apparently cured. The pain returned, however, in three days, and quinine was employed again without effect. Antifebrin was then used, and also failed to relieve the pain. Exalgine was then given in two-grain doses every four hours, and effectually banished the pain for some days. On its subsequent return exalgine proved of no service, except to permit him to sleep at night, although given in the same doses every two hours. He complained of a singular feeling of numbness all through his body after the use of the drug.

Case VII.—M. M——, female, aged thirty-five, morphine habit for three years, taken for a pain in the side. The original cause of the pain was a fall several stories down an elevator shaft. The daily amount of morphine taken for the pain is small, seldom more than three grains. The disease seems now to be a morphine neuralgia. Exalgine pills were substituted for several days, two grains every two or four hours. While she acknowledged some relief of pain, other disagreeable effects were produced—drowsiness, nausea, dilated pupils, and diarrhœa; previously there had been myosis and constipation. It is probable that the pupils appeared dilated, merely because of the relaxation of the iris from the cutting off of morphine. Patient felt compelled to return to her favorite habit, and as any quantity of morphine she may desire is provided for her by an indulgent mother, there was no obstacle to her so doing.

Case VIII.—M. A——, female, aged sixty, brachial neuritis. There was first a severe brachial neuralgia, with a herpetic eruption over the whole extent of the median nerve. After recovery of the herpes, there was intense pain and tenderness along whole arm, particularly about fingers and wrist, and with trophic changes in the skin and muscles of those parts especially. For the amelioration of the pain exalgine was given first in pill form, later in the form of the cordial exalginque, in doses of some two grains each, every four to six hours. The effect has been excellent. The cordial seems the better form for administration in this case, and has been relied upon for three weeks as an analgesic. No ill results have followed its use.

In addition to these eight cases, of which notes are given, exalgine was given experimentally in some twelve cases of various forms of cephalalgia, in the two grain doses several hours apart, and with benefit in about fifty per cent. The doses, as is evident, have been minimal, and where the analgesic quality of the remedy has not manifested itself, it is probable that double or triple quantities at one dose would have proven efficacious. Upon the whole no bad effects were produced, except, possibly, some in the case of morphine habit, and in certain of my cases it was a decidedly useful medicament. The doses employed by the French physicians who introduced the remedy were, as has been stated, from four to six grains, and from my experience I should in most cases begin with four-grain doses every two to four hours. With smaller doses the analgesic effect may be uncertain in its development.

201 West Fifty-fourth Street.

---

The Owner of Hunyadi Janos.—David Andreas Saxlehener, owner of the Hunyadi Janos, who died recently, was an uneducated but sharp-witted man. He was in the clothing business at Budapest, when a peasantre marked in his store that he had very bad luck in boring wells for water on his farm, getting only an ill-smelling liquid that he feared to use. Saxlehener procured a sample of the water, had it analyzed, bought the peasant's farm, and became many times a millionnaire through the sale of the water.—*Medical and Surgical Reporter.*

## UTERINE HEMORRHAGE AND LIGATION OF THE UTERINE VESSELS AS A THERAPEUTIC EXPEDIENT.

By JOHN A. MILLER, M.D.,

SALT LAKE CITY, UTAH.

Ligation of the uterine vessels for uncontrollable hemorrhage, I believe, originated with the late Carl Schroeder, of Berlin, accompanying or preceding his "high amputation of the uterine cervix;" at all events, I had never heard of this surgical expedient before, nor have I seen it referred to since in any of the medicals journals which chanced to come into my hands. It was in 1884, when I was a student in the Martin Clinic, that I witnessed Dr. Martin precede his operation for the vaginal extirpation of the uterus with a ligation of the uterine vessels, and that he often removed the uterus without the loss of more than half an ounce of blood was one of the most striking features of his method of operating. In our country this surgical resort is very little known, or at least noticed or practised. Only a few weeks ago an estimable lady, and mother of several children, bled to death, because the hemorrhage from the uterus was beyond the control of those remedies which are ordinarily employed in such cases. In this case the bleeding was the result of an artificially induced abortion, which had been decided upon by her medical advisers to check obstinate vomiting.

I can simply say that I have resorted to this surgical expedient on three different occasions, where all else had failed, and the results were immediate and all that could be wished for; and, had I not passed a ligature through the lateral aspect of the fornix of the vagina, high up and into the uterine tissue, the patients would all have died.

Uterine hemorrhage is a relative term; to uterine diseases it bears about the same significance as a cough does to pulmonary affections. Hemorrhage of the uterus depends on so many diversified pathological processes that one cannot have an intelligent idea of the remedial resource in a given case until a thorough examination clears up the relation of cause and effect; so it is not my purpose to enter into the etiology, but to outline a surgical expedient which never can fail to arrest hemorrhage, no matter what the cause, in the unimpregnated uterus.

To make the subject thoroughly understood, I have compiled the anatomy of the blood-supply of the uterus in as few words as possible.

The arteries supplying the uterus, beginning from the fundus down to the cervix, would be, first, the ovarian arteries; as these and the others are double, I can limit myself to the description of one side. The ovarian artery arises from the aorta, and when it arrives at the pelvic brim it passes inward between the two layers of peritoneum, forming the broad ligament. The artery passes beneath, on a lower plane than the Fallopian tubes and ovaries, so that the small branches which supply the tubes and ovaries from the ovarian run directly upward, while the main ovarian, according to Hyrtel, runs tortuously toward the upper angle of the womb, and there divides into two branches, of which the upper supplies the fundus, and the lower branch anastomoses at the side of the womb, near the isthmus, with the uterine artery, which is larger in calibre than the ovarian and arises from the internal iliac. This artery passes inward to the neck of the womb; here it ascends in a tortuous manner on the side of the organ, and distributes small branches (the curling arteries of the uterus) to the substance of the organ. Near the isthmus there is a special branch of the uterine, which joins its fellow of the opposite side, forming the circular artery.

Now it will be interesting to notice that the indirect blood-supply to the uterus, when the former branches are ligated, must come from the vaginal arteries, which, anastomosing, form the azygos vaginæ, and that running up joins the circular artery of the uterine. If we keep this simple and clear picture of the blood-supply of the uterus in our mind, we can at once see how easy and practicable it is to cut off entirely the arterial supply of the womb. This is virtually done by Dr. Martin in the preliminary steps to the vaginal extirpation of the uterus, and the result is invariably as above stated—no hemorrhage.

The ligation of the uterine vessels is neither difficult to perform nor dangerous to the patient if ordinary skill and care are employed.

The first step in the operation is to thoroughly disinfect the vaginal canal by using a large quantity—two or three gallons—of carbolized warm water of a two and one-half per cent. solution.

The patient is then placed in the perineal lithotomy position, and, by means of a bullet-forceps or some similar instrument hooked into the vaginal portion of the cervix, the womb is pulled down to the vulva. A Simon's or Sims' speculum is used to open up and retract the posterior commissure of the parts, while the assistants, who are supporting the legs of the patient, by means of blunt retractors retract the labia majora et minora; this latter retraction is not always necessary. To an assistant is also intrusted the bullet-forceps, and he at the same time deflects the organ to the side opposite to that on which you are about to pass the ligature. This will give full scope for manipulation. With the index-finger the operator now locates the body of the uterus, which it is intended to include, or at least so much of it as will assure the certainty that nothing but broad ligament and uterine tissue is insnared in the ligature, for it would not be desirable to include the Fallopian tube, and decidedly dangerous to stretch the intestines. From what has been said on the distribution of the blood-vessels, it is obvious that it is not necessary to carry the ligature too high up or too far outward from the body of the womb to insnare the vessels, and, by keeping close to the body of the uterus, and not going higher than the upper end of the middle third of the body, there is absolutely no danger of wounding the intestines.

A strong curved needle, one and three-quarters of an inch long, is armed with a strong double ligature; the left index-finger supports the tissues and the uterus, while with the right hand the needle is passed near the cervix, in front and toward its side, through the fornix of the vagina, from before upward, backward, and downward, and out through the fornix again, near its point of entrance. This is then tied, and the other side is proceeded with in a similar manner. After twenty-four hours both ligatures may generally be removed, there being no further danger from hemorrhage.

I will mention here that curved needles are not passed by straight or direct pressure, it requires a curved or circularly directed force, otherwise the needles will break. A little practice with a curved needle on a piece of leather will impart the necessary proficiency. To practise on the patient is too late, and may result in failure.

In conclusion, I would like to suggest the ligation of the uterine vessels for the cure of pathological processes of a hypertrophic and inflammatory nature.

Heretofore great benefit has been derived from local depletory measures like glycerine tampons, scarifications, and hot irrigations; the results would be astonishing in some instances where the disease is too obstinate to yield to mild measures. The congestion and swelling of the uterus, incident to flexions, would also come under this head, especially those cases where reposition of the organ is made impossible from inflammatory adhesions. An enlarged uterus might in that way be starved into smaller proportions.

---

The Fifth International Congress of Otology will be held in Florence in 1892. The following subjects for discussion are already announced: 1. The "Pathological Anatomy of Inflammation of the Middle Ear." 2. "The Diagnosis of Cerebral Abscess caused by Ear Disease." 3. "General Therapeutics of Ear Diseases."

## THE USE OF THE TAMPON IN PREGNANCY.[1]

By GEORGE H. NOBLE, M.D.,
ATLANTA, GA.

Mr. President and Gentlemen: This little paper is presented to you with the hope that in it you will find something of value to the practical man, as it treats of a subject that has engaged a part of my attention for the past eight years. During that time this treatment has been applied to a number of cases, and demonstrated fully to my mind the value of the method.

I desire more especially to call your attention to the mode of treating old lacerations in the pregnant uterus; but, first, shall briefly mention some other conditions in which it may be used with benefit.

My first applications of glycerine on cotton or wool, for profuse and irritating vaginal discharges in pregnancy, were made in 1881. In this way many troublesome and almost intractable cases were relieved, especially when due to turgescence of the pelvic blood-vessels. The remedies usually associated with it are palliatives or neutralizers of the secretions.

Following close upon this, it was employed in some instances of nausea and vomiting with very satisfactory results. I was led to its use by the observation that in some vascular disturbances of the pelvis reflex phenomena were more pronounced and distressing. This (unlike Graily Hewitt) was attributed to the engorgement, and not directly to flexions and versions. However, I endeavored not only to relieve the engorgement, but also to correct the displacement; as the relief of the former without the latter was irrational and disappointing, though occasionally it afforded some temporary relief with the uterus in an abnormal position.

Its specific action I was unable to explain; but since invoking the aid of Bretonneau's theory I have assumed that it augments the stretching of the uterine fibre by distention of the blood-vessels. Barnes anticipates me when he says that "the immediate irritating cause we believe to be due to stretching of the uterine fibre under the excentric pressure of the growing ovum, and to turgescence of the uterine vessels. This turgescence receives a sudden increment under the hydraulic pressure which takes place on assuming the erect posture."

Granting, then, that turgescence of the uterine blood-vessels is an important etiological factor, the glycerine dressing, through its detergent action and support afforded the pelvic viscera, becomes a remedy most likely to meet the demands of the treatment indicated. The combined effect of the glycerine and the pressure promotes softening of the cervix, thus enabling that portion of the uterus, so susceptible to reflex neuroses, to stretch without demonstration of nervous phenomena.

The tampon can avail but little in retroflexions and retroversion of the gravid uterus, as it is far inferior to a well-fitting pessary, unless tenderness is sufficient to prohibit the use of the instrument. In this case the glycerine treatment should be employed to pave the way for the pessary.

If the displacement is complicated by impaction sufficient to render reduction impracticable, the glycerine may reduce the swelling sufficiently to permit replacement of the organ by carrying off the water in the engorged structures. Spiegelburg used it for this purpose, recommending frequent changes and the use of the T-bandage.

Impaction of the anteflexed uterus is so rare that some authors doubt its existence. Just here it may be well to mention that by impaction we do not mean a gravid uterus of development just large enough to well fill the pelvis, and requiring more or less skill in its reduction, but one that has become so jammed in the true pelvis that it is immovable without exerting force sufficient to endanger the safety of the ovum.

Impaction may, however, occur with the anteflexed uterus if there is contraction of the posterior ligaments by parametritis and anterior adhesions to the fundus, thus acutely anteflexing the uterus and fixing it in the anteverted position. In that case the development would be downward as well as upward, and it would most likely become impacted if gestation progressed far enough, or unless the adhesions give away.

A case of this kind presented herself to me with the uterus acutely anteflexed and anteverted. The cervix was drawn high up to the sacrum, while the fundus was engaged beneath the pubic arch. The impaction was extreme, and correction impracticable without relieving the swelling by the glycerine and light elastic pressure of the wool, which accomplished the desired results.

Other cases may be relieved in the same way, though they are apt to abort, or to be recognized before the development reaches that point where the swelling alone is sufficient to cause impaction.

Sacciform dilatation and hypertrophic elongation of the cervix in pregnancy may be treated by the tampon with a view of affording mechanical relief. Lusk recommends it in the latter disease.

For prolapsus of the pregnant uterus I know of nothing better. Here again the tampon has the indorsment of Lusk, Spiegelburg, and others. It must be continued until the uterus is large enough to remain above the pelvic brim, and should then be gradually diminished.

In prolapsus of the vagina the tar ointment, one drachm to one ounce of vaseline, is a most valuable remedy applied on a light tampon to the vaginal mucous membrane, avoiding contact with the cervix. It shrivels the mucous membrane equally as well as hot water, sometimes, I am inclined to think, better, as the corrugations from the tar seem to remain longer than those from the hot water, when the patient is placed in the knee-elbow position.

Dysuria from pressure is one of the most common troubles in pregnancy, and one of the easiest to relieve. Often a few small pledgets of cotton with glycerine or vaseline, under the base of the bladder, will give instant relief. It is not always necessary to take the weight off the uterus, for a simple support to the base of the bladder will often answer the purpose.

*The Tampon in Lacerations of the Cervix of the Pregnant Uterus.*—Perhaps there is no accident so common in labor as laceration of the cervix, and certainly none more prone to cause premature expulsion of the ovum in subsequent pregnancies.

The engorgement and swelling commonly found in laceration of the cervix are greatly intensified in the gravid uterus. The lips may swell until they virtually roll inside out, adding increase to the irritation and turgescence of the pelvic vessels. These symptoms, conjoined with the increased weight of the uterus and the softened condition of the neck, constitute some of the principal elements requiring consideration in the treatment. Swelling, eversion, granulations with a tendency to oozing of blood, and hemorrhages, are the most serious symptoms, for they are almost always accompanied by pain and uterine contractions. The vaginal portion may swell to more than three inches in diameter, or even half fill the vagina, the extent of which bears some proportionate relation to the gravity of the case, but not to the extent of the laceration. I have had the most aggravated symptoms with slight tears, and have observed trivial disturbances from deep ruptures. One of my cases, at the fourth month of gestation, had slight prolapsus, with the cervix so swelled and everted that it occupied at least half of the vagina. The finger passed without resistance directly into the patulous canal, until it came in contact with the membranes. The everted surface was raw and granular, and bled freely on slight friction with cotton. The laceration was unilateral, and apparently an inch and a half deep. Uterine contractions were frequent and forcible. Abortion seemed imminent, but she was safely carried to term and delivered of a living child. A pessary was applied before she was permitted to leave the bed, as is my custom with patients

[1] Read before the Medical Association of Georgia, April 19, 1889.

who have been subject to displacement. When the pessary was removed, six months afterward, I was very much astonished to find that the laceration, instead of being an inch and a half in length, was only a mere nick or fissure in the side of the os.

The sagging usually found in the non-pregnant uterus may become a prolapsus when pregnancy occurs, and render formidable a case that would ordinarily give but little discomfort. When associated with a slight tear it may cause more trouble than a rupture into the vaginal junction; but when coupled with the latter, it is apt to be a serious and delicate case to handle. Fortunately the latter class of cases is in the minority; though, if the true status of affairs was known, it would probably prove to be the cause of abortion in many cases that do not fall into the hands of the physicians.

The objects to be accomplished in the treatment are:

1st. Correction of the displacement, which straightens out the tortuous blood-vessels, and in this way relieves obstructions to the flow of the blood (Emmet).

2d. The relief of turgescence, which is accomplished by the detergent action of the glycerine.

3d. The support of the structures, which prevents recurrence of the trouble; and,

4th. Softening of the cervix, which permits stretching of the uterine fibre without nausea.

The application should be cautiously made, small pledgets of wool, often only a single one, well saturated with glycerine, should be applied and increased gradually from day to day, as the turgescence is relieved and tolerance established, until a quantity sufficient to correct the displacement or support the structures is employed. After the uterus is developed sufficiently large to remain above the true pelvis, the tampon should be reduced gradually in order to avoid discomfort, and to observe whether or not the vascular disturbances return. Some discoloration of the mucous membrane and distention of the vessels must be expected after the discontinuance of the dressings, as it is a physiological condition of pregnancy, and should be given consideration only when it goes beyond the border line and becomes pathological.

In that case a continuance of the treatment is indicated. If the secretions are very profuse, the tar ointment or dry tannic acid sprinkled in the lower part of the vagina will be of great service in preventing expulsion of the wool. Particularly is this useful in prolapsus and eversion of vagina.

If there be great tenderness, glycerine in large capsules has proven serviceable; but a better thing is the glycerine suppository. These are soft and less liable to act as foreign bodies. These I have used in several cases preparatory to the wool-dressings, introducing them into the vagina with the hips elevated, to prevent the escape of the glycerine. However, there are but few cases that will not bear the wool treatment from the start, unless it be those with a tendency to bleed from fungi, or granulations of the os. To the latter it is best to apply a thin layer of glycerine-soaked cotton, to protect it from the hard wool fibre, which will abrade or cut through the epithelium of delicate mucous membrane. To such cases the administration of iodide of potassium is serviceable, either in constitutional disease or in defective local nutrition.

If the symptoms are not serious nor the eversion extreme, they may be relieved in a few weeks or months; but if, upon the other hand, the symptoms are grave and the swelling and eversions very great, the treatment may have to be continued until the case approaches near the close of gestation. After shortening of the cervix has occurred (in the latter months of pregnancy) it is not so liable to become swelled and everted.

The longest time I have continued the treatment was five months, ending in the seventh month of gestation. This was in a delicate woman, who, before coming into my hands, had been subjected to numerous treatments for a number of years. She had chyluria, hemorrhoids, and other distressing symptoms. She was at the second month of pregnancy, with the cervix greatly swelled and everted, the os granular, the uterus slightly prolapsed, and the pelvic vessels distended. The treatment relieved all these, but had to be continued up to near the eighth month, as an interruption was always followed by an indication of relapse. The laceration was unilateral, and very slight in extent.

Another case, who had had one premature labor and one abortion, presented most alarming symptoms. The swelling of the cervix was enormous, it half filled the vagina. The os was raw and bleeding, the lacerations were unilateral, and apparently an inch and a half deep, and the uterus was prolapsed to the floor of the pelvis. Uterine contractions were frequent, and abortion seemed actually in progress. Yet she progressed favorably under the treatment, which had to be be continued until the end of the sixth month before it could be left off with safety. The entire weight of the uterus was sustained by the dressing until it was large enough to remain above the brim.

During the treatment of this case the patient was entirely free of pain as long as the dressing remained in the vagina, but as soon as it was expelled and the uterus allowed to come down, the uterine contractions would return and continue until a fresh dressing was applied.

Now I cannot impress upon you too strongly the distinction between this treatment and the tamponing commonly and imperfectly done in gynecology. It is not the hard packing used in the hemorrhages and other conditions, but, at first, a simple pledget of wool intended as a means of applying glycerine to the swelled and tender structures. Then, after it has accomplished some relief, it is carefully increased as the improvement will permit, until it has effected the desired results.

The pregnant uterus can be educated up to tolerance of foreign matter in contact with the vaginal portion, especially if it is to be the means of relieving symptoms or disease more dangerous than the foreign body itself. Taking this view of the matter, the glycerine dressing, when used with good judgment, is a safe[1] and valuable treatment, particularly for old lacerations in the pregnant uterus.

*Summary of Cases.*—Of sixteen retrodisplacements ten had retroflexions; the remaining six were simple versions. Four were treated primarily with glycerine dressings to pave the way for the pessary. Ten had pessaries applied at once—thus all eventually were replaced by pessaries.

Of the ten retroflexions eight had lacerations, one of which had been repaired, but hypermetropic elongation of the portio media remained. The uterus was very soft and flaccid, neither pessary nor cotton would keep it in place, so as a last resort a flat, elastic stem-pessary was employed with success. One was treated conjointly with vaginal pessary and small dressing, as the laceration caused such extensive eversion that the pessary alone would not answer the purpose.

Of twenty-two cases of profuse and irritating vaginal discharges eighteen had some displacement; seven, retroflexions, included in previous list; one, anteflexion; ten, prolapses in various degrees. Of the eighteen, six had lacerations. Of nineteen cases of laceration eight are included in the ten cases of retroflexion, and six in the list of profuse and irritating vaginal discharges. The remaining five were slight tears, with slight prolapses or sagging, more than is normally found in the early months of pregnancy.

Of the nineteen cases of laceration, fourteen had bilateral rupture, six of which extended into the vaginal junction; five of these has a history of repeated abortions. The lacerations in the remaining one occurred at the confinement of the preceding pregnancy.

One of the last five miscarried four weeks after discontinuing treatment, caused by ill-treatment from her husband. Three cases with slight lacerations presented alarming symptoms, but did not abort.

[1] In a series of thirty-three cases no unpleasant symptoms have appeared, except a sense of fulness when the dressing was carelessly applied to a non-displaced uterus.

## SEVERE CASE OF INSOLATION; HISTORY, TREATMENT, AND RECOVERY.

By R. ELLIS, M.D.,

PEEKSKILL, N. Y.

The patient, a large, muscular man of forty-two, employed in a sugar-house, felt indisposed the day before, but continued his work; and, despite the advice of his friends, persisted in going to work the next morning. He "felt bad all over," yet kept on working in a very hot room till, at 5 P.M., his fellow-workmen saw him fall forward on his chest against an iron sugar-receiver.

His clothing was loosened, and water was poured over his head until the arrival of the ambulance, which hastily brought him to the hospital.

I found the man unconscious, face pale, hot, and covered with profuse perspiration; respiration sighing and very weak; sphincters relaxed; pulse, 160; and temperature, by rectum, 109° F.

The patient, without being moved from bed, was stripped, a rubber blanket placed under him, and ice-water thrown from a height of four feet all over him; tr. digitalis, ℥ x., and whiskey, ℥ xx., were given hypodermically, and the pulse and temperature taken every few minutes. Great care was taken to disturb the patient as little as possible; the sphincters were so sensitive that the introduction of the thermometer was followed by loose, watery fæces.

5.30.—Pulse has responded very slightly to the stimulants; respirations still very feeble and sighing; temperature, 108.6° F.; occasional involuntary passage of fæces.

6.00.—Pulse, 140, very weak and compressible; temperature, 108.2° F.; convulsive stage beginning; face slightly turgid.

6.15.—Convulsive stage well marked; arms extended and raised straight above head; legs, fingers, and toes flexed; face very turgid; jaws tightly locked on piece of cork to prevent injury; no attempts made to restrain patient; loud sighing cry with every expiration.

6.30.—Pulse slightly better; temperature, 107° F.; legs and arms now extended; body so stiff that patient can be raised by heels and head; occasionally an opisthotonic spasm comes over patient, lasting but a few seconds, when body is rigidly extended again.

6.45.—Convulsive stage so severe that a hypodermic of morphia, gr. ¼, with atropine, gr. $\frac{1}{120}$, was given, which seemed to quiet patient greatly.

7.00.—Pulse, 120, feeble and occasionally intermitting; temperature, 106° F.; ice-water still continued, yet stopped occasionally and entire body rubbed briskly toward the heart with dry towels; tr. digitalis, ℥ x., hypodermically.

7.30.—Pulse slightly stronger; temperature, 105° F.; ice-water and rubbing continued, body being red from the rubbing; fæces still passed involuntarily.

8.00.—Temperature, 103.6° F.; pulse, 110; ice-water discontinued; patient's body dried and removed to adjacent dry bed, care being taken to keep body horizontal while being moved.

8.30.—Skin, though red, is still cold from effects of the ice-water; temperature, 103° F.; pulse, 90, with ten intermissions; convulsive stage not marked, yet attempts at flexion show body is still rigidly extended; eyes now open, with a look of intelligence; does not answer questions.

9.00.—Temperature, 103.4° F.; patient now covered with towels squeezed out in ice-water; ice-bag to head; temperature quickly fell below 103° F., only to rise again when towels were removed. Interesting to notice that the temperature is so much under the control of the physician that the cold towels lowered the temperature below 103° F. several times, only to rise again when the towels were removed, till, finally, temperature remained at 102.8° F., great care having been taken to avoid too sudden a fall from 109° F., especially when the temperature had fallen to 104° F.

9.15.—Patient covered with sheet and light blanket; temperature, 102.6° F.; pulse, 80, with twenty intermissions. Tr. strophanthus, ℥ x., with whiskey, ℥ xx., were given hypodermically. In five minutes there were but eight intermissions, in fifteen minutes but four, pulse being much stronger. Patient did not recognize his daughter, seemed sleepy, and hence the light was turned down and quiet enjoined.

10.00.—Temperature, 102.4° F.; skin naturally warm; pulse, 100; looks frightened when touched, but seems much relieved when he is reassuringly patted.

10.30.—Gave his name, and answered questions intelligently, though with a very thick tongue.

11.30.—Patient has slept quietly, yet not deeply; pulse, 90, no intermissions; temperature, 102.2° F.

12.00.—Improved; temperature, 102° F.; pulse, 90; ice-bag kept on head, and patient left with the nurse for the night.

8.00 A.M.—Very bright; temperature, 99.5° F.; pulse, 72, full and strong.

2. P.M.—Temperature normal; patient able to leave hospital, only sequelæ being two swellings over pectoral muscles, resulting from patient's fall.

In conclusion, let it be said that—

First, every case is a law unto itself.

Second, every case should be treated *immediately*, even while being carried home or to the hospital.

Third, the condition of the heart and temperature is the basis for all treatment.

Fourth, do not reduce temperature too rapidly below 104° F.

Fifth, patient must be disturbed as little as possible, and must not be left for a moment until he is either dead or on the road to recovery.

# Clinical Department.

## REPORT OF A CASE OF TUBERCULOUS NEPHRITIS, WITH AUTOPSY.

By J. H. REILLY, M.D.,

FAIR HAVEN, VT.

I was called on April 11, 1888, to see S. B——, aged seventeen, whose family history was very obscure, and found her suffering from severe pain in the region of the bladder. She stated that her trouble commenced about two years previous by pain in the region of the bladder and frequent micturitions, which afterward became very painful. This attack confined her to her room for about two months. From this she recovered and became well enough to attend school. Between the first attack and the present one she had two acute attacks, running about the same course as the first one. She had noticed a gradual loss of strength since her first attack. She had no cough, pain in the chest, night-sweats, nor any history of rheumatism. Her last trouble commenced about two weeks previous to my seeing her. She complained principally of frequent painful micturitions and constant pain in the region of the bladder. I made a general examination and found her much emaciated and very anæmic. I could not detect any abnormal condition of the lungs. The area of cardiac dulness was not increased, but a systolic murmur could be heard over the aortic orifice, which I attributed to her anæmic condition. There was no tenderness in the lumbar region, but palpating over the region of the bladder caused great pain. There was no abnormal condition of the urethra found. Œdema was not present. The urine which had accumulated in the vessel showed a large quantity of pus. Thinking it a case of chronic primary cystitis, I directed my treatment to that organ. I tried to wash out the bladder with a solution of biborate of soda, but the meatus, which was excoriated, was very sensitive, and not having any cocaine with me I did not succeed. The next day, after applying

to the meatus a ten per cent. solution of cocaine, I succeeded in passing the tube of the Davidson syringe into the bladder, but that organ was so sensitive that it would not tolerate over an ounce of the solution, and I also injected into it two drachms of the solution of cocaine; but the whole procedure was so painful that I had to give up the attempt. I prescribed for her a pill containing benzoate of soda, 4 gr.; ergotin, 1 gr.; ext. of hyoscyamus, 1 gr., to be taken every three hours, and also a tonic of iron, arsenic, and strychnine, and a diet consisting principally of milk. An examination of the urine revealed at this time a large percentage of albumen; the microscope showed a large quantity of pus, epithelium, and phosphatic crystals. I did not discover any casts at this time, but three weeks later hyaline casts were present in abundance. Her condition during the next month was somewhat improved, but not to any great degree. About June 1st, which was six weeks from the time I had seen her, the vesical symptoms were more aggravated; gastric disturbance had commenced, and a slight cough had developed, with pain over the apex of the right lung. Hectic fever was also present, with evening exacerbations. An examination of the lungs at this time revealed dulness and moist râles over both apices and the left base. Later on, tubal respiration could be heard, and the expectorated matter from the lungs was purulent. From this time up to the middle of August, when she died, her vesical pains were very severe, and could only be partially controlled by keeping her on large doses of morphine. The autopsy showed that emaciation had reached an extreme degree. Tubercular deposits were found all through both lungs and pleura, which were firmly adherent in places. Nothing abnormal was found about the heart. The liver was in a healthy state. The right kidney was large and pale, its capsule adherent. No tubercular deposits were found through it. On opening the left kidney about an ounce of pus was found in its pelvis, and a pyramidal-shaped tubercular deposit had taken the place of each pyramid, some of which had broken down in the centre, and the cavities which were connected with the pelvis were also filled with a greenish, purulent material. The ureter connected with this kidney was about half an inch in diameter, and its walls were very thick. The walls of the bladder were very much hypertrophied; its cavity was contracted. At the opening of the left ureter there was a large ulcer, probably produced by ichorous pus from the kidneys. Its mucous surface throughout was congested and roughened by elevations about the size of a pin's head, which I supposed were miliary tubercles. The peritoneal glands were in a state of tuberculous degeneration. The mucous surface of the stomach was also congested. The spleen was found in a normal state. The brain was not examined.

I think there can be little doubt as to which organ the primary trouble originated in. From the fact that her trouble dated back almost three years, and that pulmonary symptoms manifested themselves only two months before she died, I think it is safe to assert that the kidney was the organ primarily affected, and that the deposit in the lungs was secondary to it. That the bladder was the primary seat of the deposit I think we can exclude. If this were the case, the probability is that instead of the disease making its way up one ureter, it would be apt to involve both. There was also some doubt as to whether the elevations I referred to as existing in the bladder were tubercular or not. There was no ulceration in the bladder, only what was at the opening of the ureter. Roberts, in his treatise on urinal diseases, states that in primary tuberculous nephritis the urinary symptoms are the most prominent from the commencement of the deposit until the termination of the disease, while secondary deposits rarely give rise to any distinct symptoms, and that the deposits in secondary cases are minute, varying in size from a pin's head to a pea, and that they are scattered over the surface and through the cortical substance of the gland chiefly. In this case the cortical portion of the gland was free from the deposit. In fact, the deposit was confined only to the secreting portion of the gland.

Great stress is, by some observers, given to the variously shaped epithelium cells found in the urine as a means of differentiating diseases of the kidney from those of the bladder. From the condition found at a late stage of the disease this means of differentiating would lead to deception. Tubercular deposits taking the place of the tubules, and the pelvis being devoid of epithelium, the urine could only contain bladder epithelium, and, reasoning in this way, our diagnosis would be referred to the bladder. Dr. Schmidt, in a late article in THE MEDICAL RECORD, speaks of palpation of the ureter as a means of diagnosing diseases of this nature, and cites a case of secondary tuberculous nephritis in which he diagnosed the condition by finding the tubercle bacillus, and by palpating the ureter, and from other symptoms referable to the kidney. In his case he could feel the ureter on the left side for about an inch from the bladder, enlarged and tender.

Primary tuberculous nephritis, says Dr. Roberts, rarely runs its entire course without the occurrence of tubercular deposits in other and unconnected parts of the body.

## A CASE OF POISONING FROM OPIUM SMOKING.

BY JOSEPH COLLINS, M.D.,

NEW YORK.

CASES of opium-poisoning are, unfortunately, not among the rarities. The unusual avenue of entrance of the drug in this case, however, prompts me to report it. It will be seen that the symptoms differ somewhat from those produced by opium when taken in the ordinary way.

The patient was a youth, twenty-one years of age, well educated and refined, of a very nervous disposition, and a descendant of a family in which the neurotic tendency is well pronounced. He had been an "opium fiend," as opium-smokers term themselves, for upward of three years, and had suffered a previous but milder attack about seventeen months before.

When first seen the patient was laying on the floor beside a smoking outfit, vainly endeavoring to cook a last pill, which he knew would add to his danger. He was very much emaciated, face haggard, and presenting the characteristic sickly pale yellow look of the opium-smoking *habitué;* eyes dull and expressionless, pupils contracted; respirations reduced to about 12 or 13 per minute; pulse feeble and rapid; intellect sluggish, although answering rationally. From his companion I found that he had been smoking almost incessantly for the preceding two or three days, averaging about one hundred and twenty pills, of three to five grains each, in the twenty-four hours. He had not partaken of food or stimulants during this period, and was further weakened by an attack of vomiting and diarrhœa, which had set in a day or two previously.

The patient was put to bed, a drachm of brandy administered hypodermatically, coffee as much as the stomach would allow, and further smoking interdicted. His symptoms, however, became aggravated, and the following morning found his respirations reduced to 10 per minute; pulse, 130, and very weak, and the *morale* of the patient extremely bad. He complained of an indescribable gnawing sensation in the stomach, and extreme restlessness; could not be retained in one position more than a few seconds; had hallucinations, and imagined that each minute was an indefinite period; his mind continually hurrying from one subject to another that had engaged his attention in his previous career. Koumiss and brandy were given, as much as the stomach would tolerate, and $\frac{1}{120}$ grain of atropia hypodermatically every three hours, until the respirations reached 16 per minute. The following night, although his general condition was better, restlessness and insomnia seemed to be aggravated. The ordinary hypnotics—as chloral and sulfonal—did not have the least

effect in producing sleep, and as rest was now the most important factor, I decided to administer one-half grain morphia hypodermatically, which was done with the result of quieting him a very little. The succeeding day, coffee, koumiss, and champagne were given in turn, with the effect of bringing his respirations and pulse to nearly a normal condition. The restlessness and uneasiness of mind were influenced by the morphia when given subcutaneously, and then only in a slight degree, although doses averaging from one-half grain to two grammes were administered.

After a continuance of this condition for three or four days it was thought advisable to allow the patient to return to smoking small quantities again, as it was only under promise that no attempt would be made to break the habit that he consented to have any treatment whatsoever. An expert cooker was therefore obtained, and the patient allowed six pills, of two grains each, at one séance, not to be repeated more than three times a day. This was about one-tenth of his former quantity. From the first smoke he began to improve, and in a week's time his *yui yan*, as these poisonous symptoms are called, had nearly disappeared, leaving his nervous system in a very shattered condition.

There is an opinion abroad that opium-smoking is confined almost entirely to Celestials. Unhappily this is not the case. I have heard it estimated by a very well-informed gentleman, himself a smoker, that there are between eight and ten thousand "fiends" in New York City to-day; and to one who has not had intercourse with this unfortunate class of people it is scarcely possible to picture their miserable existence. I have now under treatment a lady, formerly an actress, who was obliged to forsake her occupation, society, and its pleasures and obligations, merely because it was impossible for her to pass any two consecutive hours without resorting to the solacing pipe.

No form of taking opium enslaves its victim so thoroughly as does that by the respiratory tract. The will-power and *morale* of the *habitués* are entirely abrogated. They will beg you to assist them to escape from its inthralment one moment, and forcibly resist you from making any endeavors to help them the next.

I consider it next to impossible to cure any patient of the habit without the aid of a well-regulated sanitarium under the charge of a competent physician and attendants, who can keep the patient under continual surveillance and treatment; and then very rarely, I fear, except by the substitution of one form of slavery, although a milder one, for another.

149 Lexington Avenue.

## A PECULIAR CASE OF TERTIARY SYPHILIS OF THE THROAT.

By E. HARRISON GRIFFIN, M.D.,

Attending Surgeon of Throat and Nose Department of Bellevue Hospital Out-door Poor, New York.

On March 1, 1889, Mr. F—— came to consult me at my office, complaining of a bad cough which kept him awake during the night, and made his throat painful from its incessant character during the day. He had been under treatment for two months previous, taking cough-sirups and morphine, and had been advised to eat rare meat with cayenne pepper, and drink as much liquor as he conveniently could. He was gradually growing worse day by day.

An examination of his larynx had never been made for this trouble. He had seen me once, two years previous, for a slight cough, which yielded quickly to treatment, and rendered a second visit unnecessary. He came with his wife, whom I was treating for a stenosis of the nose of syphilitic origin. A thorough examination at this time failed to reveal any syphilitic symptom.

Upon his second visit, two years later, I found, while examining his larynx, a deep ulceration and partial loss of the epiglottis, with heavy ulceration of the true and false cords, and ulceration in the sinus pyriformis.

I made my diagnosis, from the appearance of the ulceration and his past history, as syphilis of the larynx. He gave the history of chancre, twenty-five years previous. In the meantime he had been in good health—a little rheumatism, a slight catarrh, but never any serious illness. When he came to me he breathed with great difficulty, and his appetite had completely gone. His cough was incessant.

The history of the case and the appearance of the ulceration could leave no doubt of the stage to which the disease had progressed. I stopped all his previous treatment, saw him daily at my office, and treated the parts locally with Dobell's solution, tannic acid in solution, cocaine, voschano-oil spray, and the application of iodoform in powder over the ulceration. Internally I began with the potassii iodidi, gr. xx., and gradually increased to a drachm, three times a day, and had the hydrarg. oxidi rubri rubbed in over his neck three times a day.

The patient's stomach stood the doses of potassii iodidi and did not revolt, neither was there any acne. At the end of five days he complained of a slight pain in the bowel, with a diarrhœa attended with a bloody discharge. I thought this might be due to his inunctions of mercury, and ordered a smaller quantity to be rubbed in. His throat did not improve as rapidly as tertiary cases usually do to doses of iodide. One day it was better, and the next day it was worse. When I stopped the mercury his pain was less severe in the bowel, but the healing process of his throat was at a stand-still. I gradually decreased his potassii iodidi, and at the end of ten days discontinued it entirely, and put him under the one-thirty-second part of a grain of hydrargyri bichloridi in solution three times a day, and inside of a week was gratified to find my patient's throat markedly improved. Once or twice I had occasion to give him potassii iodidi in four-grain doses; but, as certain as I was to combine the iodide, I would find the ulceration on the increase in a few days.

Among the large number of these cases that I have been called to treat in private practice and in the Bellevue Out-door Poor Throat Clinic, this is the only one I have ever seen that yielded to hydrargyrum alone, and in which potassii iodidi did absolutely harm. His wife was able at one time to take one hundred grains three times a day, and, in fact, it was only by this dose that I was able to give her any relief from her symptoms.

The patient made a perfect recovery under the latter treatment, and gained twenty pounds in weight. I have heard since that the patient had been given up by his previous attendant, who had diagnosed his trouble as consumption of the lung.

An examination of the larynx is sometimes a very important factor in the cure of a case.

112 West Forty-fifth Street.

---

Trading in Practices.—A lawsuit in England recently revealed a curious trade carried on by a young physician named Hanna. Soon after obtaining his license to practise, being then twenty-two years old, he bought a practice at Bingley for £250, and sold it thirteen months later for £650, though the purchaser does not appear to have been altogether satisfied with the transaction. He then went to St. Leonard's and bought a practice there for £185, but was not very successful in this venture and had to sell out for £275. Then he turned to Coventry, and bought the practice of Dr. Aitkens for £297, including the furniture. Here he took a partner, who paid £500 for the privilege of sharing in a practice which was represented to be worth £950 per annum. Soon after this Dr. Hanna became bankrupt in some unexplained way, and when taken to court the history of these transactions came out.

THE MEDICAL RECORD:

## SOME SUGGESTIONS CONCERNING NOMENCLATURE.

LANGUAGE is intended to be the medium through which ideas are expressed, and in order that it may fulfil this purpose, it is of the utmost importance that the words used should have a definite meaning, and one that is expressive of a certain idea. This is especially true in science, and here, even more than elsewhere, the words of the writer or speaker should be carefully selected, and should be distinguished, as Dr. Pye-Smith has well said, by clearness and conciseness. There are several terms in medical nomenclature which are used in defiance of this axiom, and concerning which a few words may be useful.

One of these is the use of the word gland as applied indiscriminately to any collection of tissue whatever. Most authorities now employ the term strictly in the sense of a secreting body, and apply the word nodes or nodules to the enlargements occurring along the lymph-vessels, or to the collections of lymph-tissue in the intestines and elsewhere. This is a good distinction, and one that it would be well if writers would observe generally, since it tends toward the side of clearness and definite meaning.

There are two other points of medical nomenclature referred to by Dr. Donald Macalister, in *The Practitioner* for August, 1889, concerning which the writer offers some pertinent suggestions. The first of these is the distinction between tubercular and tuberculous. By most writers these two words are used synonymously, or rather interchangeably, without any attempt to separate them in meaning. The author suggests that the adjective tubercular be used only to denote a morphological appearance, implying a condition in which small nodules are apparent, being thus nearly synonymous with nodular. The term tuberculous he would employ solely as the adjective corresponding to the noun tuberculosis. Similarly, he would use the terms tubercule and tubercle to denote respectively the morphological cutaneous nodule and the specific granulomatous nodule.

A second suggestion made by Dr. Macalister is concerning the employment of the terms diphtheritic and diphtherial. The former word, he points out, is used in two very distinct senses, as relating to one of the forms of inflammation, or to the specific disease, diphtheria. "Pathologists," he says, "classify the inflammations of the mucous membranes as (1) catarrhal, characterized by a morbid increase of secretion with desquamation; (2) croupous or fibrinous, when there is an exudation from the vessels which coagulates on the epithelial surface and forms a separable false membrane; and (3) diphtheritic, when the exudation induces coagulative necrosis of the mucous membrane, and the false membrane formed is separable only as a slough. Necrosis and coagulation are the essential features of diphtheritic inflammation, and it may be due to various causes. The diphtherial virus, when it affects the pharynx and neighboring parts, may, according to its intensity and the state of the patient, set up either catarrhal, croupous, or diphtheritic inflammation; it by no means always induces the latter form. On the other hand, acute dysentery is often diphtheritic, though it has nothing to do with diphtheria. The neuritis of diphtherial paralysis is not a diphtheritic inflammation. It would be impossible to make this latter statement in a clear and concise form if the distinction here drawn were not observed, and therefore I would propose that diphtherial should refer to the specific disease diphtheria, while diphtheritic is reserved for the variety of inflammation, whether it be induced by the poison of diphtheria or not."

It would be well, we think, were these distinctions observed by writers on medicine, for they certainly are a step toward that clearness and conciseness in language which are so essential to a correct understanding of it.

## AN AËRIAL HOSPITAL.

THE value of high altitudes in the treatment of pulmonary phthisis is generally recognized at the present day, though unfortunately the number of sufferers who can avail themselves of this therapeutic measure always has been, and always will be, limited. Only the favored few are so situated that they can leave their occupations and can afford the expenses inseparable from a long journey and a prolonged stay in localities where the conditions are favorable for arrest of tuberculous disease. Again, the separation from home and friends is trying, and the depressing influences of nostalgia are often sufficient to more than counteract the benefits of climate and soil.

These drawbacks, however, are now to be done away with, for an ingenious Frenchman, Dr. Riera by name, inspired doubtless by a climb to the topmost platform of the Eiffel tower, has devised a means whereby high altitudes may be brought, as it were, to everyone's door, and an elevation of one, two, or five thousand feet may be reached in less time and with no more exertion than are involved in a street-car ride of a dozen city blocks. The accomplishment of this object is to be attained by means of a captive balloon of large size, beneath which is suspended a commodious hospital, provided with all the conveniences and luxuries of the best hotels on *terra firma*. The house can, of course, be raised or lowered to any elevation desired. Communication with the ground may be had by means of cars travelling upon the cables attached to the balloon. By means of telephones the inmates of the hospital can converse with their friends, or be entertained at evening concerts and lectures. The library will contain a full set of Jules Verne's works, and will be free to all. The opportunities for exercise would necessarily be somewhat limited, but the roof of the house could be used as a promenade, and the stronger and more

adventuresome of the patients might climb down and up the anchoring cables by way of getting up an appetite. Among the therapeutic measures employed as adjuvants to the high-altitude treatment, gaseous enemata would doubtless be popular, for the balloon could be tapped at any time, and if the gas were returned after use there would be no danger of reducing the level of the house.

We cannot refrain from extending our congratulations both to the originator of this brilliant scheme and to the many seekers after the hitherto unattainable which is now within their grasp. It is thus that science triumphs over all obstacles. Old age has been robbed of its terrors, and now the consumptive can sit in his eyrie and laugh at the bacillus of Koch.

### A REPORT ON CIGARETTES.

MR. WILLIS G. TUCKER, analyst to the New York State Board of Health, has sent in a report on the result of his examination of various popular brands of cigarettes. Statements are often made that cigarette tobacco is adulterated with opium or other agents, and that the paper wrapper contains various injurious substances. Careful analysis of tobacco and paper failed to reveal any poisonous ingredients other than the tobacco itself; and the examination tended to show, what is probably true, that most cigarettes contain pure tobacco and good paper. The evils of cigarette smoking are, as Mr. Tucker states, due to the fact that cigarettes are cheap, convenient, and can be used in large and excessive quantities, that the smoke is usually inhaled, and that children and immature persons so freely use them.

## News of the Week.

DR. HABERSHON, of London, died on August 22d. He was author of a work, well-known in this country, on diseases of the digestive organs.

SOME PERSONAL EXPERIMENTS WITH HANGING.—At the recent Congress of Forensic Medicine in Paris, Dr. Gosse, of Geneva, opened a discussion on hanging and described experiments made upon himself. On two occasions he had so far succeeded in hanging himself that he entirely lost consciousness. He found often that the cord did not squeeze the throat so as to stop the breathing. The rope formed a sort of triangle which pressed on the carotid, but not on the larynx. In that case death was not painful, there was a buzzing sound in the head, and unconsciousness at a very early stage. But if the rope pressed on the throat, then the struggle for breath was very painful. On carefully examining criminals after hanging, it would be found that when convulsions occurred the lungs were empty. If the victim could fill his lungs with air before the rope tightened he would not suffer so much, if at all. When a person was found hanged and there were two marks showing that the rope had changed place, this might be considered as a suspicious sign. It, in all probability, meant that he had been hanged after having been strangled. This he had noticed in the case of a gendarme hanged on the Swiss frontier. There were two marks, so he made a more careful investigation, and then perceived that the rope was too short for the gendarme to have been able to hang himself. Ultimately, what seemed a suicide was proved to be a murder.

SPONTANEOUS COW-POX.—Dr. E. Morrison, of Newton, N. J., September 4, 1889, reports a case which he believes to be one of original, or so-called spontaneous, cow-pox.

THE CHICAGO *Medical Journal and Examiner* has suspended publication.

ACCORDING to the *New England Medical Monthly*, President Timothy Dwight, of Yale College, has secured the title of "LL.D." for a homœopath to whom he felt indebted for professional services. This homœopath is furthermore said to have "given public documentary evidence of his small learning and less wit."

A NEW MEDICAL COLLEGE.—The U. S. Grant University of Chattanooga, Tenn., has organized a medical department which opens this fall.

TREPHINING THE LATERAL VENTRICLE.—In a case of severe tubercular meningitis marked by coma, slow pulse, Cheyne-Stokes respiration, fixed dilated pupils, and twitchings in one arm, Professor von Bergmann trephined the frontal bone and tapped the lateral ventricle. The immediate effects were excellent; consciousness returned, the pupils reacted to light, the pulse and respiration became more natural, and all went well as long as the cerebro-spinal fluid continued to escape through the puncture. But this drain ceased, the serious symptoms then recurred. and the child died.

AMERICAN ACADEMY OF MEDICINE.—Dr. Richard J. Dunglison, secretary, announces that the annual meeting of the Academy, for 1889, will be held at Chicago, Ill., November 13th and 14th, being postponed to that date by authority of the Council.

AN OFFICIAL INVESTIGATION OF ARTIFICIAL FOODS.—At the recent meeting of the Association for the Advancement of Science, Dr. F. Hoffman, of this city, read a paper on infant foods, in the course of which he stated that the chemists of the United States Agricultural Department were about to begin with the work of investigating the different artificial foods and infant foods now on the market.

MEDICAL CONGRESS IN BRAZIL.—The second Brazilian Congress of Medicine and Surgery will be held at Rio de Janeiro, beginning on the 15th of this month. The meeting will be presided over by Dr. Hilario de Gouvêa. Among the subjects for discussion the following are of general interest:—"The Nature, Cause, and Treatment of Beri-beri," "Prophylaxis and Treatment of Yellow Fever," "Prophylaxis and Treatment of Tuberculosis," "Geographical Distribution, Symptomatology, Nature, and Treatment of the Acute Spasm of the Œsophagus, which is endemic in certain parts of Brazil," "The Nature of Ainhum," "Elephantiasis Arabum," etc.

ORRIS ROOT IN AMERICA.—Florentine orris (*iris florentina*) is said to have been discovered in considerable quantity growing in South Carolina.

THE THIRD ANNUAL MEETING OF THE AMERICAN ORTHOPEDIC ASSOCIATION will be held in the building of the Boston Society of Natural History, at the corner of Boylston and Berkeley Streets, on September 17, 18, and 19, 1889. The following papers have been announced: Address by

the President, Dr. E. H. Bradford, on "American Orthopedics;" "Spondylitis after Typhoid Fever," by Dr. V. P. Gibney, of New York; "The Relation of the Thoracic and Abdominal Walls to the Spinal Column, considered with Reference to the Treatment of Anterior-posterior Curvature," by Dr. L. A. Weigel, Rochester (by invitation); "Psoas Contraction as a Symptom," by Dr. Dillon Brown, New York; "Double Congenital Dislocation of the Hip," by Dr. Samuel Ketch, New York; "A Case of Caries of the Ankle treated Conservatively," by Dr. C. C. Foster, Cambridge; "A Report of Cases of Caries of the Ankle treated by Excision (with exhibition of patients)," by Dr. Charles L. Scudder. Boston (by invitation); "The Value of Motion in the Treatment of Hip Disease," by Dr. W. R. Whitehead, Denver; "Rest in the Treatment of Hip-joint Disease," by Dr. De F. Willard, Philadelphia; "Abscesses in Hip Disease, their Prevention, Significance, and Treatment. A Clinical Study," by Drs. R. W. Lovett and J. E. Goldthwaite, Boston; "A General Discussion upon the Treatment of Hip Disease," by Drs. Shaffer, H. L. Taylor, J. E. Moore, Steele, De F. Willard, R. H. Sayre, Ridlon, Gibney, and others; "An Experimental Study of Distraction of the Hip-joint," by Dr. E. G. Brackett; "An Analysis of Twenty-one Cases of Hip Disease treated by the Thomas Splint," by Mr. John H. Huddleston; "The Treatment of Pes Equino Varus," by Dr. Henry Ling Taylor, New York; "Is Rotary Lateral Curvature of Rachitic Origin?" by Dr. G. W. Ryan, Cincinnati; "A New Exercise in the Treatment of Lateral Curvature of the Spine," by Dr. A. J. Steele, St. Louis; "The Treatment by Portative Appliances of Ununited Fracture of the Thigh," by Dr. Newton M. Shaffer, New York; "Operations upon the Spine for the Relief of Pressure Paralysis, with the report of a case," by Drs. Herbert L. Burrell and W. N. Bullard, Boston (by invitation); "A Case of Functional Torticollis, probably due to defective eyesight (with exhibition of patient)," by Dr. R. W. Lovett, Boston; "A Case of Congenital Absence of Five Ribs, with resulting Deformities," by Dr. Homer Gage, Worcester (by invitation); "The After-treatment of Hip Disease," by Dr. A. B. Judson.

Sam Jones on the Faith Cure.—In a recent sermon Sam Jones delivered himself as follows concerning the faith-cure brethren: "I'll tell you where this faith cure comes in. There's an old brother and sister who have been taking all the nasty quack patent medicine on the market for the last ten years. Somebody comes along and prays over 'em, and they quit using the patent medicines, and they are well again. They say it was faith that cured. It was faith. It was the faith which caused them to quit taking old patent nostrums which cured them."

An International Congress of Hypnotism.—Paris is congress-mad, and the number of so-called international congresses held there during the exposition season is legion. One of these was devoted to the study of hypnotism. The objects of the meeting were to determine upon a nomenclature for the new science, and also to collect and record facts illustrating the therapeutic value of the new method. Among the recommendations set forth by the congress was, that all public exhibitions of hypnotism should be prohibited, that the exercise of this force as a therapeutic measure should be placed under the same rules and restrictions that govern the practice of medicine, and that the study of hypnotism and its practical application should form part of the regular medical curriculum in the schools. The following is the somewhat clumsy definition of the hypnotic state as formulated by one of the essayists, M. Berheim: Hypnosis is a particular psychic condition, susceptible of being induced, which increases in varying degree the suggestibility of the patient, that is to say, the aptitude of being influenced by an idea accepted by the brain, and of realizing it.

Examinations for the Medical Corps of the Army.—An Army Medical Board will be convened in New York City, N. Y., October 1, 1889, for the examination of such persons as may be properly invited to present themselves before it as candidates for appointment in the Medical Corps of the Army. Application for an invitation should be addressed to the Secretary of War, stating date and place of birth; place and State of permanent residence, and accompanied by certificates, based on personal acquaintance, from at least two persons of repute, as to citizenship, character, and moral habits; testimonials as to professional standing, from the Professors of the Medical College from which the applicant graduated, are also desirable. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular Medical College, evidence of which, his diploma, must be submitted to the Board. Further information regarding the examinations and their nature may be obtained by addressing the SurgeonGeneral-United States Army, Washington, D. C.

A Latin Periodical.—Alongside of the Volapük enthusiasts there are a few men in this country, as well as in Europe, who are working to reinstate Latin as the language of science, if not of general communication between the nations of the world. These may be encouraged to learn that a periodical, written in chaste and elegant Latin, has recently appeared in Aquila degli Abruzzi, in Italy. It is edited by Carlo A. Ulrichs, a young Latin scholar of considerable reputation, and is published semi-monthly. Six numbers have already appeared, and the editor announces that the subscription-list is increasing in a very satisfactory manner, and contains the names of many scholars in Europe and America. The name of the periodical is *Alaudæ* (Larks). It is a purely secular journal, being filled with poems, stories, anecdotes, jokes, and news. An effort is being made, it is said, to establish a medical journal in Latin, but the success of such an undertaking would seem to be very problematical at this time.

The "Annales de la Tuberculose" is the name of a new journal recently established in Paris. It is to be published bi-monthly, and, as its name implies, will be devoted to a study ot tuberculosis in all its aspects.

The British Medical Association adjourned without deciding upon any place of meeting for 1890. It was supposed that London would invite the members to assemble there; but there is a want of harmony among the members of the medical profession in London just at this time, so the invitation was not forthcoming. No other place has expressed a desire for a visit from the Association.

A New Source of Supply of Podophyllum.—It is said that the May-apple grows in great abundance in the

Himalaya mountains, and that it is very much richer in podophyllin than the American plant, the amount of resin which can be extracted from it being nearly three times larger than that from the podophyllum of this country.

M. PASTEUR has been created a baron by the Emperor of Austria, for distinguished services.

DR. J. J. SHANKS has resigned the superintendency of the Flatbush Insane Asylum, and gone to Europe.

HOMŒOPATHISTS IN AUSTRIA.—According to the most recent official statistics in Austria, there are only 118 homœopathists out of the whole number of medical men, 7,183, and only 44 of these profess to practise homœopathy exclusively. There are none at all in the Italian districts, and only 19 in Vienna. The number also is said to be steadily decreasing.—*Medical Press.*

SMALL-POX is said to predispose one who has suffered from it to contract tuberculosis.

THE MOTT MEMORIAL LIBRARY.—One of the funniest institutions in this city, says *The Sun*, is the Mott Memorial Library. Dr. Valentine Mott left it behind him because he could not conveniently carry it into another world, and it has since been maintained as a public institution. It is strictly medical, chiefly surgical, almost entirely confined to the period of twenty-five years ago. The library and various busts and portraits of its original owner are housed in a delightful old brick mansion in Madison avenue. The books are carefully locked in cases, and seldom consulted. The whole house is exempt from taxation. Of course, it is wicked to tax a free library. Meanwhile, however, the rooms in which the unused library is situated are rented to various organizations.

THE CORNER-STONE OF THE DELAWARE HOSPITAL, in Wilmington, was laid August 18, 1889. The cost of the grounds and building when completed will amount to $20,000, $16,000 of which is in hand.

SURGEON HARVEY E. BROWN, U. S. A., died August 20th, at Jackson Barracks, near New Orleans. He was a son of General Harvey Brown, of the regular army, and born in New York. He graduated from the University Medical College in 1858. He was surgeon of volunteers from 1861 to 1863, and then became Assistant Surgeon, U. S. A.; became full Surgeon and Major in 1881. He was the author of a valuable compilation and historical sketch of the Medical Department of the Army from 1775 to 1873. He was identified with nearly every epidemic in the Gulf District for twenty-five years. His final disease was lingering and painful, due to consumption.

JOHNS HOPKINS UNIVERSITY RUINED.—The New York *Sun* prints a long communication from Baltimore, describing the financial condition of the Johns Hopkins University, and claiming that it is now practically ruined. The endowment was nearly all in Baltimore & Ohio R. R. stock, which once paid ten per cent. dividend, but now pays nothing. We note, however, that the University has just received a legacy of over $100,000 by the will of John W. McCoy.

VIRCHOW ON THE DARWINIAN THEORY OF THE ORIGIN OF MAN.—Professor Virchow, at the recent session of the Anthropological Congress at Vienna, again attacked Darwin's theory of the origin of man. "It is now," he said, "twenty years since this doctrine of triumph has reached us, that we had only to find the connecting link between man and monkey to complete our history of race and varieties; but our labors since then have been fruitless in discovering that important connection, the 'vormensch,' or that particular 'pro-anthropos' which would enlighten our path. Since the promulgation of this theory many stormy wars have been fought, but now we are inclined to believe that every human race has come from a race of human beings, and not from the monkey tribe at any time."

SUICIDE OF DAVID TILDEN BROWN.—Dr. David Tilden Brown, Superintendent of Bloomingdale Asylum, from 1855 to 1875, committed suicide at his farm, at Batavia, Ill., on September 5th. Dr. Brown was the victim of sensational journalism. In 1875 a New York paper began a bitter fight against the Bloomingdale management, because of alleged outrages carried on there. This attack so affected Dr. Brown that his health failed and his mind became unbalanced. In this condition his wife took him abroad for treatment. His insanity was of a mild form. In an Edinburgh asylum a partial cure was brought about. The doctor and his wife returned to America. In an Illinois asylum, where Mrs. Brown secured a position as matron, the cure was completed, and with what money he had left Dr. Brown bought a small property in Batavia, Ill., on which he has since lived happily. His son, Dr. F. T. Brown, lives in this city. A few weeks ago, a New York daily came out with a sensational account of Dr. Brown's history, and a statement that he, though believed dead by all his friends, was alive. The publicity given to this story is said to have acted upon Dr. Brown's sensitive mind, and produced an attack of melancholia. Dr. Brown was a man of fine attainments, a very popular man, and an accomplished physician.

JUGULATING PNEUMONIA.—At the recent Therapeutical Congress, in Paris, M. Petrescii, of Bukharest, claimed that pneumonia could be aborted in its early stages by giving large doses of digitalis, *e.g.*, 4 to 8 grammes (3 j. to 3 ij.) of the leaves in infusion, daily.

DR. J. G. JOHNSTON, of Brooklyn, who was recently arrested under charges of criminal assault, has been, we are told, entirely exonerated.

IT IS STATED THAT MR. REGINALD HARRISON, F.R.C.S., of Liverpool, who is well known as an authority and a skilful operator in diseases of the urinary organs, is about to take up his residence in London.

THE SECOND ITALIAN CONGRESS FOR INTERNAL MEDICINE meets at Rome, October 15 to 18, 1889. Among the subjects to be discussed are malarial infection, nephritis, and gout.

ORTHOMETHYLACETANILIDE is the name for exalgine, found by Dujardin-Beaumetz to possess very marked analgesic properties.

OVERHEAD ELECTRIC WIRES IN LONDON.—Attention was called recently in Parliament to the danger from overhead wires in London, and an effort is being made to have them put underground.

## BRITISH MEDICAL ASSOCIATION.

*Fifty-seventh Annual Meeting, held at Leeds, England, August 13, 14, 15, and 16, 1889.*

(Special Report for THE MEDICAL RECORD.)

(Continued from page 275.)

### SECTION OF MEDICINE.

WEDNESDAY, AUGUST 14TH—FIRST DAY.

DR. JOHN E. EDDISON, of Leeds, delivered the

PRESIDENT'S ADDRESS,

which consisted merely in a few words of welcome and a brief sketch of the work proposed for the Section. He remarked that in his opinion it was wrong to so far divide the study of medicine, and he much regretted the excessive multiplication of sections. Thus medicine was split up into sections of therapeutics and pathology, and there seemed to be a tendency to make the medical section into a mere place for the discussion of the symptomatology of disease, a fatal error, he thought.

DR. R. DOUGLAS POWELL, of London, then began the work of the Section with a communication upon

THE CLINICAL ASPECTS OF CHRONIC TUBERCULOUS DISEASE OF THE SEROUS MEMBRANES.

He said he would not enter into the detail of symptoms before such an instructed audience, but merely give a few general observations on tubercular diseases of serous membranes in different regions of the body. Tubercular disease was sometimes a primary affection in the pleura, the joints, the cranium, and the peritoneum, and was often localized in one serous membrane, so that the symptoms produced were due to the presence of tubercle in the part. It was said that in such cases the tubercle bacillus effected an entry into the region from the outer surroundings of the patient; but he agreed with Mr. Barker, who had observed that a certain state and condition of the tissues seemed necessary for the appearance of tuberculosis in any part. Thus in children the cells of the embryonic tissue were less resistant to the invasion of the bacillus than those of adults in certain localities. Thus simple inflammatory disease of a joint might lead to the invasion of the bacillus from lessened resistance. In children of the ages between three and nine the tissues were remarkably vulnerable; but after the age of nine it was rare to see tubercle in the joints. This period (three to nine) was a period of great excitement. Tubercular meningitis was rare in adult cases of consumption; thus in 563 cases of that malady occurring in Brompton Hospital, London, only 30 suffered from that form of it. Tubercular meningitis as a chronic disease was so rare as to be almost unknown. It proved fatal so rapidly that it was not one of the instances of chronic tubercular disease of the serous membranes, so that he need say nothing about that kind of affection of the serous membranes. Pleurisy, he observed, was known to precede tuberculosis in many cases, and it was often difficult in such circumstances to ascertain whether there might not be, simultaneously with the pleurisy, some deposit of tubercle in the lungs. He mentioned a case of pleurisy which had been under his care nine years previously, and which he had brought before the notice of the International Medical Congress in London. In this case he had drawn off the serous fluid, and the patient was confined to bed for sixty days, and left the hospital with a contracted left lung. Last year, 1888, this patient had extensive tubercular disease of the same lung. In another case a girl, in 1885, had been treated for pleurisy with effusion, and in 1888 she exhibited symptoms of phthisis pulmonalis of the left apex, with many bacilli present in the sputum. In this case there had probably been some consolidation of the pleura previous to the occurrence of the pleurisy in 1885. In the sputum there were lime salts present, and very likely there had been some arrest in the progress of the tuberculosis and deposit of lime salts around a small cavity which was not recognized when the pleurisy was present. He drew attention to the

DIAGNOSTIC POINTS

in ascertaining the presence of tubercle in such difficult cases as this. Of such were slight hectic, slight cough, and wasting of the body. Perhaps tubercular disease might be found to exist in other organs. Dry pleurisy at the apex of the lung was a very suspicious symptom, and Dr. Burney Yeo had given interesting cases where such dry pleurisy of the apices had existed without tuberculosis. In some cases the sputum was tinged with blood. Then, again, too little attention was often paid to slight rising of the temperature in such cases. In some instances of tubercle in the lungs the temperature might only rise to 99° F. in the evening; but, if this continued, it was of very great importance as a point in diagnosis. Then as to the effusion, in most cases the fluid was perfectly pure. When stained with blood this might lead to the suspicion of the existence of tuberculosis or cancer. Setting aside cases of pneumo-thorax, pus was rather the exception in such cases of pleurisy than the rule. In twenty cases of pleuritic effusion in consumptive persons there was a total absence of bacilli in the effusion. This was ascertained, firstly, by microscopic observation; next, from cultivations with the fluid, which proved fruitless; and, lastly, from the results of inoculation of the lower animals with the effusion, although the last of these processes had been the most positive in its results in similar cases. Yet in some of these cases the pleuræ were found after death to be studded all over with tubercles. In one case he had seen, a gentleman had gone to Corfu, and while on that island had experienced a chill while travelling. Shortly after this the patient presented symptoms of softening of the right base of the lung. The temperature fluctuated in this case, and it apparently was one of simple pleurisy; but it turned out to be a case of phthisis. In his case he examined the effused fluid repeatedly for bacilli, but at first found none, and it was only on the seventh examination that a few were seen. In another case of empyema he had procured a drop of pus from the pleural membrane itself, and this showed bacilli. He asked,

WHAT BECOMES OF CASES WHERE ABSORPTION TAKES PLACE?

In such cases the tubercle became obsolescent, and the prognosis depended upon the condition of the lung itself. With regard to the thickening of the pleura, a hard, thick, cartilaginous pleura was not a concomitant of tuberculosis. These are the cases in which pneumothorax occurs in phthisis pulmonalis. In the case of tubercular peritonitis the diagnosis of the disease was of great difficulty in the outset of the case. Friction might sometimes be heard. The pulse was quicker than usual, and the temperature heightened, although it had a lower range than in tubercular pleurisy. Then there was loss of flesh and some ascitic effusion. This ascites might in the female simulate ovarian dropsy. In one case which he had seen the woman looked quite as if she was suffering from ovarian disease, but this was not the case. Then there was the case which had been published by Sir Spencer Wells, in which there was a prominent abdomen, and when the abdomen was opened the peritoneum was found to be studded all over with tubercles. Sir Spencer Wells stitched up the abdomen, and the patient recovered. This was twenty-six years ago, and he had heard that the patient was alive.

Of thirty-eight cases collected in which the abdomen had been opened in similar circumstances, sixteen of the patients recovered their health. He was not sure whether all of these were really tubercular peritonitis. In another case cited by the author masses could be felt agglutinat-

ing the intestines together, the tongue was glazed, and the pulse quick. In another case, which proved fatal, there was complete strangulation of a knuckle of intestine, and Dr. Fenwick had noticed this cause of death in some cases. Louis' dictum, that when, in an adult, there was tubercle in any organ of the body, there would also be found to be tubercle in the lungs, was almost, but not quite, true. The tendency of tubercular disease was to produce fibroid degeneration in cases where pleuritic effusion had existed for a lengthened period. The pelvic portion of the peritoneum was almost a separate sac, and was often entirely shut off from the general peritoneal cavity. In his experience two cases of tubercular peritonitis had been diagnosed as neurasthenia, and had been treated by massage, which had proved fatal to the patients. As a clinical phenomenon, it must be conceded that tubercular peritonitis was not necessarily a fatal disease. In the tunica vaginalis testis the appearances were similar to those seen in pleurisy.

THE PROGNOSIS OF TUBERCULOSIS IN THE PLEURA AND OTHER SEROUS MEMBRANES WAS NOT HOPELESS,

but, of course, very alarming. No drug we were acquainted with had the power of curing tubercle; neither iodoform nor any any other antiseptic possessed such power. Perhaps mercury, pushed to salivation, might occasionally kill the bacillus; but all other parasiticides were too feeble, so that all that could be done was to strap the chest in pleurisy, or depend on other palliative remedies. With regard to operations, great differences existed as to the operative treatment to be employed in joint tubercle, for while one surgeon would operate early and frequently in such cases, another would but rarely operate, and when he did so would do it late on in the disease. General tubercular disease in other organs might be lighted up by the spread of the bacillus from one organ. Effusion in other organs might be salutary in cases of tuberculosis of the lungs. The idea of opening the peritoneum in tubercular peritonitis would have been looked upon with horror some years ago. But Mr. Knowsley Thomson had twice operated inadvertently in such cases of tubercular peritonitis, and had had no bad results. There were, of course, favorable cases, for it was impossible to remove the disease by operation, and the successful cases were those which were not associated with perforation of the bowels.

Dr. Handford, of Leeds, agreed with Dr. Powell that tubercle could not be cured by any drug. The tubercle bacillus ran a very different course in different animals. The chief effort in therapeutics should be directed toward improving the condition of the organ affected with tuberculosis. He was by no means convinced that all the cases where the peritoneum had been opened by surgeons, and tuberculosis had been said to exist, were clearly cases of tubercular peritonitis. In some cases called tubercular peritonitis no bacilli had been found. He asked whether laparotomy was indicated in cases where no effusion existed into the peritoneal cavity. In suppurative peritonitis laparotomy might be of service.

Dr. Burney Yeo said that it would be very important in discussions if some proposition were defended and attacked, as it would save time in sticking to the question. As to tubercular disease of the pleura, this rarely took place without the lung also being affected. Certain cases of disease of the apex might occur, which were dependent on rheumatic affections. Cases like these got well, and often figured, he believed, among the cases of cure of phthisis. Other cases existed with diseases of the joints of rheumatic character, and iodine and iodide of potassium cured them. A patient of his had some signs of bronchial catarrh, but no symptoms of phthisis, *i.e.*, neither emaciation, quick pulse, night-sweats, nor hectic. She was considered to have phthisis by some, but neither himself nor some other consultants took that view of the case. He agreed with Dr. Powell that it was not very good practice to remove the effusion in tubercular peritonitis. He was in favor of antiseptics in the treatment of such cases.

Dr. Churton said that he had had recently a case of a man with tubercular peritonitis under his care, and who, although not actively treated, had quite recovered. In some cases where he had thought that the patient had been cured, tubercle had afterward appeared in the lungs. He asked whether in such cases the opening of the abdomen might not prove curative. As to diagnosis, he considered that the presence of blood in the fluid drawn off from a suspected case of tubercular effusion was not of much value as a symptom of tuberculosis.

Dr. Broadbent, of London, would say only one word as to the effect of the incision of the abdomen in tubercular peritonitis. He had not been fortunate enough to see a cure effected by this operation in any case; but in all instances in which this operation had been performed there had been some relief given to the patient. In one instance great relief was given, and life considerably prolonged. Tubercle, he observed, was a very vulnerable neoplasm, and thus this operation might cause its disappearance in the organs.

Dr. C. G. Brown said that pleurisy of the base of the lung was not infrequently followed by deposit of tubercle in the apex of the lung.

Dr. Drysdale, of London, said that the opener of the paper had alluded to the extreme vulnerability of children from three to nine years of age with regard to the tubercle bacillus in joints, and he would like to ask whether the whole human race might not be considered as vulnerable in like manner, if subcutaneous injection of tubercle bacilli were effected. This was his own belief, but he had heard it doubted by most competent persons. He had seen several cases where apparently innocent pleurisy with effusion had, in a few years afterward, been followed by phthisis pulmonalis, and cited the case of a gentleman, aged fifty-seven, who caught cold, had pleurisy with abundant effusion, from which he recovered, but three years subsequently had phthisis pulmonalis and died of the disease. This was an instance of a part becoming vulnerable to the bacillus because of an attack of inflammation. He had never detected the tubercle bacillus in pleuritic effusions, even in consumptive patients. He saw but little good in the proposal to operate in cases of tubercular peritonitis, and was afraid that this was one of the cases of the *nimia diligentia medici* which were to be avoided.

Dr. Saundby, of Birmingham, agreed that the bacillus of tubercle could not be combated by germicides, and hence

ANTISEPTIC TREATMENT WAS OF NO VALUE IN THE TREATMENT OF CHRONIC TUBERCULOSIS OF SEROUS MEMBRANES.

He was not in favor of incision in cases of tubercular peritonitis. As to the circumstances which favored the appearance of tuberculosis, he held with Professor Virchow that these were of even greater importance than the presence of the bacillus tuberculosis. Predisposition was of immense importance in the producing of phthisis pulmonalis, and the human race were by no means all equally vulnerable by tuberculosis.

Dr. Dreschfield explained how it was that tubercle became obsolescent. In his view the germs existing in the part gradually exhausted all the material requisite for their nutrition, and unless they were carried to another part where there was fresh pabulum, they tended to die, and then there was a deposit of lime salts in the cavity left by the bacillus.

Dr. Eddison thought that the good done by mercury in syphilis was not by killing the bacilli, but by making the blood antiseptic and incapable of nourishing the germ of that disease. The reason why tubercle bacilli could not be found in tubercular pleurisy was because we passed the trocar into the fluid part. He strongly objected to the vicious circle of therapeutic diagnosis which said that

because a disease was curable by mercury and iodide of potassium, it was therefore clear that it was a case of syphilis, etc. As to the question of incision into the peritoneal cavity and the discovery of the existence of tubercular peritonitis by inspection, he felt inclined to ask whether in all the cases where the peritoneum was opened and tuberculosis diagnosed, the diagnosis had been clearly made out.

MR. IMLACH, of Liverpool, said that in some cases where he had opened the abdomen he had discovered tubercle in the ovary and in the peritoneum, and there were cases in which he had operated in which he had found the peritoneum studded with tubercle. In five such cases he had expected to hear of the speedy death of the patients, but this had not taken place, although he had interrogated the friends of such patients for many months after the operation. The diagnosis of tubercular peritonitis was extremely difficult. Washing out the abdominal cavity with hot water was often of great service in such cases.

DR. DOUGLAS POWELL, in reply, said that antiseptics were useful in pleuritic effusion when there was pus present. Such antiseptics had, however, had no influence on the bacillus tuberculosis. He was glad to hear Dr. Broadbent say that incision was sometimes beneficial. As to the remark made by Dr. Drysdale, that the whole human race were vulnerable to tubercle, this referred to cases in which subcutaneous injections with a quantity of bacilli were made, and these were not comparable with ordinary cases of infection from a few bacilli. He believed that all persons might be vulnerable in such circumstances as those of inhalation of bacilli contained in spray or in liquids which were subcutaneously injected. Dr. Imlach's cases were a great contribution to the subject.

DR. CUTTER, of New York, exhibited a number of lantern-slides of the blood of tuberculous patients, and showed groups of yeast-cells which were contained in the blood of such patients, and which, he said, were easily removable by the removal of sugar from the diet of such patients.

DR. C. R. DRYSDALE, of London, read a paper on the alleged

RARITY OF PHTHISIS PULMONALIS AMONG LONDON JEWS.

The author of the paper said that there had been for some time past an idea entertained in London that conforming Jews in that city were far less liable to the inroads of tuberculosis than the ordinary population of London. This opinion had been entertained by Dr. Septimus Gibbon, and also by Dr. Maurice Davis and Dr. Behrend, of London, all of whom, experienced physicians, had spoken as if the occurrence of consumption among London Jews was excessively rare. His own experience as physician to the Metropolitan Free Hospital of London was also that phthisis pulmonalis was comparatively infrequent among the Jewish patients residing in the neighborhood of Houndsditch and the Jewish quarters of the East End of London. In order, however, to clear up this point he had made inquiries of several London physicians practising among their own brethren, and had received communications from Drs. Dyte, Kish, and Abraham Cohen, in addition to similar letters from Dr. Maurice Davis and Dr. Behrend. This evidence was conflicting, for while some of the older practitioners were very affirmative as to the extreme rarity of consumption among London Jews, the younger physicians admitted that phthisis was by no means infrequently met with among them. Dr. Drysdale had been permitted to witness the slaughtering of sheep and oxen at the Deptford cattle market, and the way in which such animals were inspected after death to ascertain whether their flesh was free from impurities, or

KOSHER.

The organ most closely examined by Jewish inspectors was the lungs, and the very smallest marks of pleurisy, or pneumonia, or tuberculosis occurring in cattle and sheep sufficed to cause the animal to be instantly rejected by the inspectors, so that about one-third of all the animals examined were rejected as unfit to become the food of orthodox London Jews. He heard, however, that perhaps not once in one thousand or two thousand cases was tuberculosis detected among the cattle examined at the Deptford cattle-market; but still modern researches seemed to have made it evident that the flesh of such animals might spread tuberculosis among such persons as partook of it. This was the cause assigned by Dr. Behrend and other Jewish medical men for the comparative infrequency of tuberculosis among conforming Jews. Dr. Drysdale's conclusions were: 1, That there seemed to be much evidence that tuberculosis was rather rare in London among Jews who eat only *Kosher* meat, although he thought the rarity had been exaggerated; 2, that tuberculosis in cattle was an occasional cause of consumption in the human race; 3, that Jews probably escaped this form of contagion to a great degree owing to the care taken by their inspectors; lastly, that it was important that such a system of examination of animals offered for food should be made by inspectors either appointed by municipalities or by private companies for the supply of meat in our cities.

DR. MACLAUREN, of Australia, said that in New South Wales there were about five thousand Jews, and in three years there had only been two deaths from tuberculosis among that population; whereas consumption was now nearly as commonly met with in Australian cities among the ordinary population as in the cities of Great Britain. He was inclined to attribute this very great immunity of the Jews in Australia from tuberculosis to their examination of the cattle used as food, many of which were affected with tuberculosis in that country.

DR. EDDISON said that in Vienna there was a good deal of consumption among the Polish Jews attending hospital in that city, and it would therefore be interesting to know whether in cases where consumption was rarely met among the Jews, as had been said, such Jews were more orthodox and attended more to their religious traditions than such Polish Jews did. In Leeds, where there was a colony of Jews, he suspected that but little attention was paid by them to the quality of the meat bought for consumption. Indeed, such Jews purchased the very poorest parts of the meat offered in the market, and consumption was not infrequently met with among them in Leeds.

DR. ACLAND, of London, said that he would gladly offer Dr. Drysdale an opportunity of continuing his inquiries in such cases at the Brompton Consumptive Hospital, where there were patients of all classes suffering from consumption. The poor suffered much more from tuberculosis than the rich, and it would be interesting to ascertain whether such Jews as contracted phthisis were more lax in their attention to the rules of diet laid down in the sacred books of their religion than those who escaped from the disease.

---

## SECTION OF SURGERY.

WEDNESDAY, AUGUST 14TH—FIRST DAY.

MR. JESSOP, of Leeds, gave a short address on the

TREATMENT OF CANCER OF THE RECTUM,

introductory to the discussion announced to take place on that subject. Mr. Jessop said that the treatment of cancer of the rectum involved distrust of the past and hope in the future. With regard to chian turpentine we might now relegate it to its proper place on the back shelves of the chemist's shop. Touching lightly on the hygienic and medicinal treatment of cancer of the rectum, Mr. Jessop remarked, among other things, that frequent washing out of the rectum with simple water was useful in many cases. Astringents were suitable in cases where the anus and sphincter were implicated and the fæces were liquefied. We should aim at obtaining simply a single daily evacuation from the bowels. Coming then to the consideration of operative procedures, he observed

that they were of two kinds, viz. (1) operations for the oblation of the disease, and (2) operations for diverting the fæces, and thus dispensing with the rectum as the channel through which to evacuate them. The former class of operations must necessarily be confined to the lower regions of the bowel; the latter were applicable to all. He would pass by operations which consisted in scraping the diseased surface and go on to consider

PROCTECTOMY.

This had only lately been forced into prominence by the success of our German colleagues. It only remained to determine in what cases it should be undertaken. In performing the operation it was of importance to secure proper drainage, to retain an efficient sphincter, and to prevent subsequent cicatricial contraction. His own cases were seven in number. Of these one died from the operation, but the patient was a poor curate, greatly reduced in health before being operated on, and he never recovered from the collapse immediately following the operation; the disease extended round four-fifths of the circumference of the gut, just above the anus. In the re maining six life was extended for varying periods. Thus one patient appeared well after twenty-one months, and another after seventeen months, from the date of the operation; while a third was unable to leave his room nine months after the operation, owing to speedy return of the disease. Proctectomy was a valuable means of prolonging life and alleviating suffering. He had not himself removed cancer from a higher part of the rectum than could be reached by the finger inserted through the anus, but he should be glad to hear the results of those who had removed neoplasms from higher portions of the bowel. He could not advise interference with cancer of the anterior wall of the rectum when the urethra, bladder, prostate, or uterus was involved. In performing the operation the patient should be placed in the lithotomy position. Either the anus should be dilated or an incision made into the rectum. He did not advise sutures to the wound. It should be kept scrupulously clean, iodoform dressings employed, and celluloid drainage-tubes used. The rectum should subsequently be washed out every eight hours with an antiseptic solution and an iodoform suppository inserted. Proctectomy was an operation of limited application in the present state of our knowledge. He had never himself removed diseased portions of bowel through an opening in the colon, but a previous diversion of fæces (as effected by colotomy) was of advantage before undertaking an operation for the removal of diseased portions of bowel and saved the patient considerable distress.

Mr. Jessop then passed on to consider

COLOTOMY.

Before asking to what extent it prolonged life, he would, he said, ask how death ensued in cases of cancer of the rectum? Of 102 patients he had seen, 17 had died from complete obstruction of the bowel unrelieved by operation, 15 had died from obstruction in cases where left lumbar colotomy had been performed, 3 had died from hemorrhage, 5 from acute septicæmia, 2 from the implication of other organs, 9 had died after left lumbar colotomy without total obstruction having occurred, and 51 had died from exhaustion. In not one of the thirty-two cases (31.4 per cent. of the whole number) in which death occurred from obstruction was the disease within easy reach of the finger passed into the bowel; in most, it was quite out of reach. In cancer of the lower half of the rectum there was not much fear of complete blockage occurring; when the upper half of the rectum was involved the opposite was the case. Mr. Jessop then referred to some cases of cancer of the rectum which had not been operated on, but which had survived several months (in one case seventeen months, in another thirty-six) without complete obstruction coming on. In cases of cancer in which the upper movable part of the rectum was the seat of the disease, we should, knowing as we did that blockage would occur, make an opening in the colon above. Excluding doubtful cases, the following were the results of 86 cases of cancer of the rectum: In 52 cases no operation was performed, and the average duration of life after the first appearance of symptoms was seventeen months. In 34 cases left lumbar colotomy was performed, and the average duration of life was twenty-two months and a half from the first symptoms, and fifty-three weeks from the date of operation. Among patients who were advised to have an operation, but who refused to submit to it, the average duration of life was thirty-four weeks. The average extension of life due to operation was therefore nineteen weeks, but we must admit that many of those cases in which operation was declined were less severe. He concluded, therefore, that colotomy did prolong life in cases of cancer of the rectum. It was a question, from observing the comparative sufferings of patients, whether it was advisable to open the colon in cases where life was not directly imperilled. The benefits of the operation were that it relieved pain, diminished the constant desire to defecate, reduced the incontinence of fæces, and enabled the patient to have one motion in the twenty-four hours discharged with ease. What kind of operation best met the condition of the patient? Inguinal colotomy had been again considered since Mr. Herbert Allingham's paper at the Dublin meeting of the Association (1587). The disease had been removed through a lumbar or inguinal opening. The present choice, however, lay between proctectomy on the one hand and some form of artificial anus on the other.

Mr. F. Marsh, of Birmingham, then exhibited a patient on whom he had performed

MADELUNG'S OPERATION,

and subsequently excised the rectum. The patient was a man, twenty-eight years of age. The colotomy was performed on March 1st last, the excision of the rectum on March 29th, and the patient was discharged from hospital on May 20th. In excising the rectum no vessel required ligature. The peritoneum was not opened, but formed the upper boundary of the wound. The case was so successful, said Mr. Marsh, that he had made up his mind in future cases of cancer of the rectum to first perform an inguinal colotomy and then excise the rectum.

Mr. Mitchell Banks, of Liverpool, then spoke, and said his experience of lumbar colotomy was confined to twenty or thirty cases. He believed the mortality was due chiefly to the condition prior to operation. He did not think one site was preferable to another for an artificial anus; the distress of having one at all far outweighed such considerations. In one lumbar operation he could not find the colon at all, so he had opened the nearest piece of small intestine. In cases of doubt it was a valuable plan to inflate the bowel with air by means of an ordinary Higginson's syringe. He agreed with Mr. Jessop as to the value of complete division of the bowel in preventing the fecal matters from passing on beyond the artificial anus. Speaking generally as to the benefit of operating in malignant disease of the rectum, he said that no doubt where there was complete obstruction an operation was desirable, but in many cases the prolongation of life for a few weeks or months, accompanied with suffering, was not a very great benefit.

Mr. Harrison Cripps said he had performed seventy operations for rectal cancer, viz., thirty excisions and forty colotomies. With regard to excision of the rectum we must select our cases. He was aghast at the mortality (thirty to forty per cent.) obtained by German surgeons. Such a mortality should cause abandonment of the operation. Here, where we selected the cases, the mortality was much less; if we did not select them, it would be as high. An operation which would be safe in the case of a middle-aged man became dangerous in an old man broken down by malignant disease. We should take care only to operate in cases where there is no constitutional infection, as of the glands or liver. Not more than four or five inches of

the bowel (as regarded height from the anus) could be removed. The growth could, in fact, be removed only when it was so near the anus that the finger could feel healthy mucous membrane above it. A movable condition of bowel was favorable to operation. If it were fixed, he would not operate unless it were fixed on its posterior wall only or on the ischio-rectal fossæ. It was unsafe and unwise to operate when the bowel was attached to the uterus or the prostate. When the recto-vaginal septum was involved he would not operate when the upper part was involved, because in such cases Douglas' pouch was mostly drawn down and the peritoneum would be opened. Kelsey's tables in America showed a mortality of twenty per cent. In his own thirty cases he had had two deaths. In the remaining twenty-eight cases recurrence had taken place in most after varying periods of time; in three cases no recurrence at all had taken place. The operation prolonged life and in comparative comfort. Pain was removed—at any rate, for a time—and even when the disease subsequently returned the pain was less severe—possibly because the sentient nerves had been largely removed. In operating, the best plan was to divide the bowel freely behind. It should not be drawn down and no sutures should be used. The wound should be plugged with lint, and a bougie be subsequently employed to prevent contraction. Passing on to the

ADVANTAGES OF COLOTOMY,

he said these were twofold, the operation gave relief and retarded the rate of growth of the malignant disease. In cases of cancer of the rectum contraction would sooner or later occur. There would be first constipation and then diarrhœa, of which the cause was not the disease itself but the accumulation above, from which a dribbling away from time to time took place. The case was similar to the overflow which occurred from a distended bladder. Colotomy took away all these symptoms and gave the patient comparative comfort. The operation should be performed as soon as there were any symptoms of obstruction. The mortality was in many cases not from the operation but from the state of the patient. In his own cases, forty in number, he had not had a single death from the operation. He had formerly employed the lumbar operation, but had lately discarded it for the inguinal operation, influenced by Mr. Herbert Allingham's advocacy of the latter. The advantages of this were, firstly, that the space in which to operate was larger; then there was less difficulty in finding and identifying the bowel. Sometimes the colon was abnormal and did not descend in the left lumbar region at all; with the inguinal operation it would be easy to detect any abnormality. Mr. Cripps remarked, in conclusion, on the advantage of early examination in cases of rectal disease so as to establish the diagnosis.

Mr. Herbert Allingham said that for practical purposes cases of rectal cancer might be divided into three groups, viz.: 1, Cases in which the growths were small, hard, and at the lower part of the rectum; 2, cases of large, ulcerating, crater-like masses; 3, cases of disease rapidly spreading and involving all the surrounding structures. He would perform excision only in the case of a small, hard growth, freely movable, within three inches of the anus, and when one could pass the finger freely above it. A point was the rapidity with which the growth could be removed. An operation for excision of the rectum usually occupied forty-five minutes, but it could be done in ten.

A PROLONGED OPERATION MEANT MORE SUBSEQUENT COLLAPSE,

because the patient was losing blood all the time of the operation. It was better to operate rapidly and check bleeding with hot spirit and water, putting in a few ligatures if needful. He did not approve of Mr. Cripps' plan of completely isolating the bowel from surrounding structures. It was best to avoid stitching down the bowel; it was likely to cause cellulitis, and often one could not bring down the mucous membrane to the skin. Colotomy, when performed, ought to be done early, and the earlier the better. As soon as there was frequent diarrhœa, pain, and straining, it added to the comfort of the patient to perform colotomy. In the inguinal operation it was a good plan to make a good spur, so as to prevent the fæces from passing on, which should render the operation useless. He thought the growth of the cancer was slower when the fæces were cut off from it, and there was also less pain.

Dr. Ward Cousins, of Southsea, said we must separate the mortality from the immediate success. Many patients came too late. If a patient lived a year after operation he considered the operation was a success; but one of his patients had lived two and three-quarters, and another five and a half years after lumbar colotomy. In the inguinal operation there was the great advantage of having the patient on his back; there was also no difficulty in finding the intestine. In lumbar colotomy the peritoneum was generally opened, and a great disadvantage was the small extent of bowel which was accessible.

Mr. Vincent Jackson, of Wolverhampton, objected to the term "inguinal" as applied to anterior colotomy, which had nothing to do with the groin. He suggested the term

ILIAC COLOTOMY.

He thought the preceding speakers had minimized the discomfort (from atresia ani) following ablation of the rectum. This was a reason for carefully considering the operation of excision. For acute cases of obstruction he advised the lumbar operation, but it was only in those cases, or where the large bowel was so distended that there was a difficulty in operating, that the front operation was not desirable.

Mr. Bennett May, of Birmingham, said patients were apt to postpone the operation of colotomy till too late. In very acute forms of cancer it was hardly worth while having colotomy performed except for acute obstruction. It was best performed for chronic obstruction; one of his cases lived two and a half years after operation. Better results had been attained since the inguinal operation, which was easier, had been introduced and the operation done earlier. He had had thirteen cases. He still preferred the lumbar operation in cases where the bowel was much distended. In the inguinal operation, also, there was liable to be excessive prolapse or excessive contraction. A moderate degree of prolapse acted as a "spur;" he believed its degree depended upon the extent to which the lumbar fascia was opened. Mr. May related a case of colectomy in which the stitches gave way, and said he should not again attempt to join together the divided ends of bowel after removing the diseased portion, but should bring both the divided ends out through the wound. In the case he had just mentioned, although he had operated early (the cancer having been accidentally discovered after opening the abdomen to perform a different operation), there were enlarged glands in the mesentery, and considerable masses of cancer in the liver.

Mr. Jessett said there were few cases in which one was justified in performing proctectomy, and even then he would prefer to perform colotomy first, and then remove the rectum.

Mr. Rushton Parker, of Liverpool, said excision of the rectum was an operation rarely advised, and the few operations which had been done were due to individual enterprise. We could not always select our cases, for patients sometimes declined and sometimes sought operations; but some of the unfavorable cases turned out well. The disease should be low down to perform excision. He had performed two operations, removing the diseased part but leaving healthy bowel at the anus; both did well. He demurred to the view that we should limit excision to cases in which only the lower part of the rectum was involved, and mentioned a case in which he had performed

excision when the lower part of the growth was four inches from the anus. Dr. Alexander's plan of incising the rectum backward, and removing the coccyx, gave great access to the rectum. By drawing down the lateral ligaments of the rectum we drew down the rectum and could open it several inches from the anus. In the case just mentioned the growth extended along the bowel for five inches, and his impression was that he divided the rectum about twelve inches from the anus. As to colotomy, by attending to diet, etc., patients could do a great deal to prevent obstruction from occurring, and thus obviate the necessity for it.

DR. INGLIS PARSONS then spoke of the value of

ELECTRICITY IN CANCER OF THE RECTUM.

One electrode was passed through the diseased portion, and another into the ischio-rectal fossa.

PROFESSOR TREUDELENBERG spoke of the advantage of operating not wholly by the knife, but partly by the fingers. Where the cancer was fixed, colotomy was the preferable operation, and the most convenient both to the patient and the surgeon. Some patients might live for twelve or thirteen years.

Mr. Lawford Knaggs and Mr. Stanmore Bishop having also spoken, the President replied, and the discussion concluded.

MR. MAYO ROBSON, of Leeds, then showed a patient on whom he had successfully performed

CHOLECYSTENTEROSTOMY

for biliary fistula. The patient had had abdominal section performed upon her three times. The first operation was for pyosalpinx, and was performed five years ago. Eighteen months ago the abdomen was again opened for acute peritonitis, with pus in the gall-bladder. The bile finally came away through the wound, and a biliary fistula resulted. From thirty to forty ounces of bile daily escaped on to the surface of the abdomen. To remedy this condition the abdomen was opened again, and the gall-bladder attached to the colon by a double row of sutures; the original opening in the gall-bladder was then sutured. Mr. Rob son said he could find no record of a case of biliary fistula previously cured. An operation had been proposed by a German surgeon for a case of obstruction of the common duct, but it was not carried out. He employed Lembert's suture to attach the gall-bladder to the intestine, but the opening in the gall-bladder was closed by a continuous suture.

DR. EASTES, of Folkestone, having narrated a case, MR. RUSHTON PARKER then read a paper on a case of

CEREBRAL TUMOR SUCCESSFULLY REMOVED.

The patient was a man, thirty-eight years of age, who suffered from long-standing headaches and weakness of the left arm and leg. There was no optic neuritis. No results followed the administration of iodide of potassium. It was not necessary to localize the tumor as there was a puffy swelling in front of the right parietal eminence, which was considered to indicate its position. The operation was successful, and subsequent examination of the growth convinced him that it was a gumma.

---

## SECTION OF OBSTETRICS AND GYNECOLOGY.

WEDNESDAY, AUGUST 14TH—FIRST DAY.

DR. CHARLES J. CULLINGWORTH, President of the Section, delivered the opening address, taking for his subject

THE APPLICATIONS OF ANTISEPTIC PRINCIPLES TO MIDWIFERY PRACTICE.

His remarks were supplementary, he said, to an address which he delivered at the opening of St. Thomas' Hospital Medical School a year ago. Antiseptic cleanliness does not consist merely in the use of some chemical disinfectant, important though that may be. But the very fact that the use of certain chemicals forms an essential part of the antiseptic method contributes to the danger of trusting to them too implicitly to the exclusion of other means of insuring surgical cleanliness. The latter may be subsidiary, but they are none the less of the greatest importance.

FREQUENT VAGINAL EXAMINATIONS SHOULD BE AVOIDED,

especially during the first stage of labor, for they are unnecessary after the diagnosis of the presentation has once been made, and only expose the patient to the danger of infection. At the Dresden Lying-in Hospital, during the years 1886–87, the number of cases admitted in whom, because of the very rapid progress of labor, or for any other reason, no vaginal examination was made was 248. Of these cases 242 made an absolutely normal recovery. The remaining 6 had slight troubles of one sort or another demanding their retention in the hospital for a few days beyond the normal time, but among them all there was not a single case of parametritis.

Another point of prime importance is

THE THOROUGH EMPTYING OF THE UTERUS

after labor or abortion. Retained matters offer a most fruitful evil for the propagation of pathogenic micro-organisms which have once gained entrance. Although the speaker did not believe in the possibility of self-infection, yet he looked upon the retention of portions of membrana placenta with as much apprehension as those who did so believe. The secundines should, therefore, be carefully examined after their expulsion, and if any part were found missing no time should be lost in exploring the uterus in order to remove it.

THE PATIENT SHOULD BE ALLOWED TO SIT UP IN BED.

This is contrary to the generally accepted teaching of the present day, yet it is merely an application of the antiseptic principle of drainage to midwifery practice. In all normal cases the speaker allowed his patients to sit up in bed occasionally, for a few minutes at a time, on the second or third day. This was in the line of practice recommended more than a century ago by Charles White, of Manchester, but it was not carried to the full extent of his recommendation.

Other points to which the speaker referred were the immediate repair of all perineal lacerations of any magnitude, and the substitution of gauze-bags of sublimate wood-wool in place of the traditional linen diaper.

THE CARE OF THE CHILD

was then dwelt upon at some length. Our zeal for the safety and well-being of the mother should not, he said, make us forgetful of the new-born infant. Antiseptic principles could be usefully applied to the management of the child in two ways, viz., in the prevention of ophthalmia and in the dressing of the remains of the umbilical cord. In the

PREVENTION OF OPHTHALMIA NEONATORUM

the speaker recommended, in addition to the wiping of the child's eyes with a clean cloth as soon as the head was born, and if possible before the eyes were opened, the application of a solution of corrosive sublimate (1 in 3,000) by squeezing over each eye a saturated pledget of cotton wool immediately after the first washing. Credé's method of dropping in a two per cent. solution of silver nitrate need only be adopted in cases where the mother was known to have suffered from a purulent vaginal discharge. The report of a committee of the Ophthalmological Society showed that from thirty to forty per cent. of the inmates of blind institutions in Great Britain and Ireland owed their blindness to purulent ophthalmia in their infancy; hence it was not unreasonable to infer that, by the adoption of the means of prevention here suggested, the amount of blindness at present existing might be diminished by one-third.

The second point in relation to the infant was

THE DRESSING OF THE REMAINS OF THE UMBILICAL CORD.

After the cord has been divided, the stump shrivels up and is finally thrown off, leaving a small, raw surface, analogous to the placental wound in the uterus of the mother, which should be as rigorously protected from the risk of septic infection.

The objects to be aimed at were to secure (1) the normal desiccation of the cord before its separation, and (2) an aseptic condition of the wound left when separation has taken place. The method recommended was, after drying the surface of the cord, to powder it plentifully with powdered starch, and wrap it in a square of antiseptic gauze. The umbilical wound should be dusted freely with finely powdered boric acid, and covered with a pad of dry absorbent wool.

In closing, Dr. Cullingworth sketched out the work which the Section had before it, and made an allusion to

THE COMBATIVENESS OF GYNECOLOGISTS.

It is true, he said, that the workers in this field are somewhat combative, and sometimes perhaps even a little wanting in forbearance toward those who differed with them. The reason of this is partly beause the study of gynecology is new, and men are still almost completely in the dark as to the pathology of some of the most common affections to which women are liable. When gynecologists know more, they will differ less. It is imperfection of knowledge that lies at the root of disputatious differences of opinion.

Dr. Braxton Hicks read a paper on the treatment of

PLACENTA PRÆVIA.

He recommended that pregnancy be terminated as soon as possible after the diagnosis of placenta prævia had been made, and said that once treatment has been begun, the patient should not be left until delivery has been accomplished. He formulated the following rules to serve as a guide in the conduct of these cases:

If the os be expanded and the placenta marginal, rupture the membranes and wait to see if the head is soon pushed into the os. If there be any slowness in this respect, employ forceps or version. If the os be small, detach the placenta from round the os, and if no further bleeding occurs, we may wait an hour or two; but should the os not expand, and if dilating bags are at hand, the os may be dilated. If it appears that the forceps can be admitted easily, they may be used; but if not, version by the combined internal and external method should be employed, and the os plugged by the leg and breech of the fœtus. After this is done the case may be left to nature, with gentle assistance, as in footling and breech cases. If the os be small, and if we have neither forceps nor dilating bags, then combined version should be resorted to, leaving the rest to nature, gently assisted. If, during any of the above manœuvres, sharp bleeding should come on, it is best to turn by the combined method in order to plug by breech.

The after-treatment should be conducted according to the modern antiseptic methods. Should oozing occur after expulsion of the placenta, swab the lower part of the uterus by styptics, and irrigate the uterus daily with some antiseptic solution. If irrigation cannot be done, iodoform pessaries should be inserted into the vagina. This is especially useful if the outlet of the uterus is blocked by adherent clots.

Dr. Murphy, of Sunderland, said that it was exceedingly hazardous to allow any case of placenta prævia to go untreated, and insisted that premature labor should be induced as soon as it is ascertained that the placenta presents, after the seventh month of pregnancy, and even before this should bleeding be serious or frequently recurring. He advised the constant presence of the medical attendant during the whole period of labor. Labor should be induced by Barnes' bags, and then the question must be decided how further to conduct it. Generally separation of the placenta, full dilatation of the os, and bipolar version would give the best results. He submitted a table of thirty-eight cases, with thirty-two consecutive recoveries. Two, only, of the cases had resulted fatally.

Dr. Lomer sent a letter, in which he advocated very strongly the method proposed by Dr. Hicks. The writer had treated twenty-eight cases by the combined method of turning, and had had but one death Thirteen of the children had been saved. After turning he made it a practice to wait, and regarded the case as one of simple foot-presentation.

TURN EARLY, BUT DO NOT EXTRACT,

was a maxim upon which he would lay special stress. Should hemorrhage continue, he made some traction on the foot so as to bring down the breech more firmly against the parts from which the bleeding occurred. The object of his traction was, however, merely to make the child act as a tampon, and was not meant to hasten delivery.

Dr. Robert Barnes began by saying that the treat ment of placenta prævia was a physiological proceeding, and that the placenta, when it occupied the lower zone of the uterus must be displaced. To do this the os must be first dilated and the membranes should be ruptured. For the purposes of dilatation he advocated the use of the bags that went by his name. He was of the opinion that detaching the placenta does not increase risk to the child. Placenta prævia, he pointed out, was a complication that when once it occurred was liable to recur in the same patient.

Dr. Robert Harvey, of Bengal, drew attention to the risk of the routine practice of rupturing the membranes, as a fresh and fatal effusion of blood sometimes took the place of the liquor amnii that had been evacuated.

Dr. More Madden described the old plan of plugging the vagina after rupturing the membrane.

Dr. Murdoch Cameron drew attention to the necessity of using new dilating bags, as the india-rubber in old ones was so liable to give way. In turning he is most particular not to insert his hand into the uterus.

Dr. A. W. Johnstone, of Danville, U. S. A., read a paper on

THE MECHANICS OF PUBERTY.

This, he explained, referred to the growth of sexual ornaments, showing that hair and feathers grow from the same kind of texture as that which lines the body of the uterus. Puberty is brought about, he said, by a general stimulation of this lymphoid tissue, and that it is its exhaustion that causes the feebleness of old age, such as change of life, and loss of permanent teeth, and senile alopecia. He exhibited drawings showing that epithelial was replaced by cell growth of connective tissue. His view explained the source of repair for the monthly loss of endometric epithelium, which is merely the lymph corpuscles of the endometrium assuming the characters of epithelium.

Dr. More Madden read a paper on

SOME POINTS IN THE TREATMENT OF UTERINE CANCER.

He thought that the disease was on the increase, and that it originates in the cervix uteri. He therefore advised timely removal of this portion. The alterative, he said, was the thermo-cautery, which was merely an improvement on the escharotics formerly employed. He traced the origin of the disease to pathological changes resulting from partial lacerations which gave rise to inflammation, and the first stage of cancer was, he thought, inflammatory. In the cases that could be traced to their end he said the disease was generally found to recur, but in fourteen of Dr. Madden's cases of removal of the cervix the result was satisfactory. He advises the cautious employment of the curette as a means of diagnosis, and advocates early removal of the intra-vaginal portion of the cervix, instead of removing the whole uterus at a latter period.

Dr. J. Stuart Nairne then read a paper on

SOME PRACTICAL POINTS IN THE SURGICAL TREATMENT OF CANCER OF THE UTERUS.

He first alluded to the symptoms of the disease, such as hemorrhage, pain, and weight in the loins, the appearance of a new-growth, the odor, etc. He referred to a series of cases which had been operated on by removal of the uterus at periods varying from eighteen to six months ago. A case of the first-named date he regarded as safe, and one of the last-named as hopeful, if there were no signs of a return of the disease. Dr. Nairne uses rectangular dilators. He scoops out the uterus and excavates till almost nothing but its peritoneal covering remains. Much alleviation is the result of these operations, and, even if nothing else was obtained, euthanasia was secured, which alone was in such cases a consummation devoutly to be wished for.

Dr. W. J. Sinclair, of Manchester, alluded to the great mortality in cancer of the uterus. In operating in such cases he now enucleates the organ, *i.e.*, he drags it down and ties it bit by bit. He drew attention to the necessity of diagnosing carefully between cancer and erosion. The sharp spoon, he said, was an effectual means of effecting a diagnosis. In the case of cancer the *débris* brought away was unmistakable, and in cases of erosion nothing but blood was taken out.

Dr. William Walter thought that if removal of the disease by operative interference was had recourse to, the whole uterus should be removed, just as you would remove the whole of a breast attacked by cancer.

The President thought the latest statistics of total extirpation of the uterus were encouraging, and said that fifty-two cases had lately been operated on in this way in Dresden without a death.

Dr. Peter Horrocks had seen a uterus removed for suspected cancer which turned out to be merely chronic endometritis. He regarded the German statistics as doubtful.

Dr. Robert Barnes also thought these statistics unreliable, and said that many cases pronounced to be cancer were really not cancerous.

The President, in speaking of the use of powerful galvanic currents, now recommended, narrated a case in which the patient died under the operation as if struck by lightning.

(To be continued.)

## INTERNATIONAL CONGRESS OF DERMATOLOGY AND SYPHILOGRAPHY.

*Held in Paris, France, August* 5, 6, 7, 8, 9, *and* 10, 1889.

(Special Report for The Medical Record.)

(Continued from page 277.)

DISCUSSION ON RINGWORM.

Dr. Butte, of Paris, related the method employed by Quinquaud and himself in the treatment of tinea tonsurans. It consisted simply in the application of a one per cent. ointment of protochloride of iodine in lanoline. Every second day the head is sprayed with warm water, and then it is dried and rubbed for some time with this ointment. It is possible by this means to cure ringworm of the scalp within a few months without resorting to epilation.

Dr. Quinquaud, of Paris, said that the method just referred to had produced excellent results in his hands. Another plan was to cut the hair very short, shampoo the head every morning, and then apply a lotion of biniodide of mercury, 3 grains; bichloride of mercury, 15 grains; alcohol, 10 drachms; distilled water, 8 ounces. After that the affected parts are scraped with a special form of curette. At the end of a week, during which time this process may have been repeated once or twice, the hairs are pulled out. Epilation is accomplished much more easily now, since the previous treatment has made the hairs much less brittle. The scraping is repeated every week or two, and in the intervals a plaster of the biniodide and bichloride of mercury is applied. A cure is thus obtained in three or four months. The children usually bear the scraping very well.

Dr. Besnier, of Paris, asked whether such vigorous treatment did not occasion a pretty active dermatitis. He had seen several cases of partial alopecia following a dermatitis caused by too active treatment of ringworm of the scalp. His plan was to cut the hair close, epilate for some distance around the seat of disease, and then apply borated vaseline. The head was washed every morning with bran-water before the application of the ointment.

Dr. Quinquaud replied that the lotion used by him caused very little irritation. There was a little redness observed for a day or two, but that was all. The plaster usually brought out a few pustules, but they caused very little inconvenience. It was well to stop all treatment from time to time in order to avoid too much irritation, but this was not always necessary, as the scalp usually became quite tolerant after a few weeks.

Dr. Besnier said that he would try this method on the strength of Dr. Quinquaud's recommendation. It should be remembered, however, that this disease was very irregular in its course. It sometimes lasted a year or two, and might again disappear spontaneously in two or three months. He recalled two cases which he had seen several years ago. The mother of the children asked him how long the disease would last, and he had replied that it was impossible to say. Six weeks later the children were brought to him again, entirely healed, and the mother said that they had been cured by Dr. Unna.

Dr. Unna, of Hamburg, said that he could not recall what treatment he had employed in this particular instance. But if the disease had disappeared so rapidly it was a matter of spontaneous cure, and could not be justly attributed to his treatment. He agreed with the last speaker as to the irregularity in the course of a ringworm. He believed, however, that it was possible to employ parasiticides which would attack the fungus without destroying at the same time the tissue in which it grew.

Dr. Vidal, of Paris, said that it was an easy matter to destroy the tricophyton when seated on the non-hairy parts. Here it was superficial, and anything that would remove the epidermis would remove also the parasite. But when the tricophyton had penetrated into the hair-follicles the matter was very different. Epilation was a delusion, for if the hair was diseased it always broke off, and only the healthy hairs could be extracted. He had made some experiments to determine the nature of this parasite, and had found that it was aërobic. Therefore if it could be deprived of oxygen it would perish. This could be accomplished by simply covering the part with vaseline. He used an ointment of iodine in vaseline (1–100), applied every day or every other day, and covered it with gutta-percha tissue, and had obtained very good results. A cure was effected in this way much more speedily than when epilation was resorted to.

Dr. Hallopeau had employed a similar mode of treatment, and was very well pleased with the results obtained.

Dr. Drysdale, of London, said that the disease was very variable in point of severity and resistance to treatment. He insisted on frequent washing of the affected part, and then used applications of tincture of iodine.

Dr. Hans Hebra said that the disease under discussion was uncommon in Vienna, and

BARBER'S ITCH

especially was very rare. He recommended the employment of a ten per cent. ointment of pyrogallic acid, by means of which, he said, a complete cure could be obtained in the course of three or four weeks.

Dr. Besnier, in concluding the discussion, said the

geographical distribution of the parastic diseases of the scalp afforded ground for much study, and its peculiarities had yet to be satisfactorily explained. Favus, for example, was never found among those residing in Paris proper, but in its environs, in country districts, and even in other large cities of France, such as Lyons, it was quite frequently met with. On the other hand, ringworm of the scalp, a very common affection in Paris, was comparatively rarely seen outside of the city. He spoke rather despondently of the therapy of ringworm of the hairy parts, and agreed with Unna in believing that a cure was usually spontaneous rather than a direct result of treatment.

DISCUSSION ON TERTIARY SYPHILIS,

including (1) the relative frequency of tertiary syphilis and (2) the conditions favorable to its development.

DR. NEUMANN, of Vienna, read a paper in which he considered the principal conditions which favored the development of tertiary symptoms. The chief of these was a neglect of mercurial treatment. It was true that cases were met with now and then which had been allowed to go untreated, and yet escaped all tertiary troubles; yet these were exceptional. Even though there had been some treatment, if this were not sufficiently active, nor long enough continued, tertiary symptoms might show themselves. Certain constitutional affections, such as malaria, tuberculosis, or diabetes, were factors in causing the apparition of tertiary phenomena, and so also were any conditions, such as alcoholism, unhealthy surroundings, old age, which tended to weaken the organism and render it less able to resist disease of any kind. Tertiary syphilis might, indeed, be seen in persons of good general health, who had received proper treatment, but it was far more common in those who had not been treated Its occurrence was in nowise dependent upon the form or virulence of the initial sore, or of the secondary manifestations.

DR. DRYSDALE had found in his own experience that the proportion of those who develop tertiary symptoms, when not treated by mercury, is eight out of every hundred. For several years he had not used mercury in the treatment of syphilis, but had lately returned to it, as it seemed to him to possess some real power in preventing tertiary manifestations, although he could not agree with Dr. Henry Lee that it was possible to cure syphilis absolutely by means of calomel fumigations. He did not believe that it was possible to form any prognosis from the appearance of the initial lesion. Nor was age a factor of any value in this regard, except that infants suffered much more severely than others.

DR. MAURIAC, of Paris, said that little could be learned from the appearance of the chancre concerning the future course of the disease. A phagedenic sore was usually followed by pretty severe secondary symptoms, but not necessarily by any tertiary manifestations. The proportion of those who suffered from tertiary symptoms was rather hard to determine, and as near an estimate as he could make was that from eighty-five to ninety-five out of every hundred escaped. The time for the appearance of tertiary phenomena was very variable and uncertain; they might come during the first year, or within a few months, and their apparition might be delayed for forty or fifty years. The average period might be set down as from the third to the sixth year. In some cases of visceral syphilis the interval was very short. The most common tertiary manifestations were those of the skin, subcutaneous connective tissue, and mucous membranes, and of the visceral forms of the disease the most important, by far, was syphilitic disease of the nervous system.

DR. FOURNIER, of Paris, in considering the time of appearance of the tertiary symptoms, said that he based his statements upon an analysis of 2,595 cases occurring in his own practice. According to these statistics the tertiary phenomena appeared with greatest frequency from the first to the third year after infection, the maximum being in the third year. From the fourth to the twentieth year it decreased gradually; between the twentieth and thirtieth years few cases were found, and it was very rare, although such cases did occur, for tertiary syphilis to show itself for the first time over thirty years after infection. The other extreme was also uncommon, nevertheless the speaker had seen 129 cases in which the tertiary manifestations were noted during the first year. As to the lesions of this stage of syphilis, the nervous affections predominated. Among his cases 1,085 were cases of syphilis of the nervous system, or, excluding locomotor ataxia (which was indirectly, if not directly, dependent upon syphilis), the number was 681. The syphilitic poison was therefore pre-eminently one acting upon the nervous system.

DR. HASLUND, of Copenhagen, presented the statistics of 600 cases occurring in his own practice. Of these 444 had either not been treated at all or had been poorly treated. In a very large proportion of cases the tertiary symptoms appeared during the first twelve years after infection. In point of frequency the cutaneous lesions held the first rank, then came the nervous system, and after that the bones and the internal organs. It had been asserted that tertiary phenomena were more common in those cases in which the lesion was extragenital, but this was due, he thought, simply to the fact that the true nature of such lesions was liable to pass undetected, and consequently the patients were not treated properly. Persons weakened by alcoholic or other excesses, or by chronic malaria, were most apt to suffer from tertiary lesions.

DR. LELOIR, of Lille, thought the division of syphilis into stages on a chronological basis was incorrect. It was not the time of appearance, but the character, of the lesion that was significant. The characteristic peculiarity of tertiary lesions was that they were essentially destructive in their nature, whereas the so-called secondary phenomena were not.

DR. VAJDA, of Vienna, said that of 632 patients with tertiary syphilis admitted to hospital in Vienna during the years 1870–77, sixty-two per cent. were found not to have had any treatment at all. The average time of appearance of the tertiary symptoms was three years and seven months after infection for those not treated, and six years and four months for those who had been treated during the earlier stages.

DR. ZAMBACO PACHA, of Constantinople, said that in his work on syphilis of the nervous system, published seven years ago, he had called attention to the remarkable frequency with which this part was attacked. His statements met with considerable opposition at the time, and he had been pleased to have them confirmed so fully by Dr. Fournier in his remarks before the Congress.

DISCUSSION ON THE TREATMENT OF SYPHILIS.

DR. MCCALL ANDERSON, of Glasgow, said that antisyhilitic treatment should be begun as soon as the symptoms of the disease had declared themselves unmistakably, but not before. The general health should be carefully looked after, but the exhibition of tonics must not be allowed to take the place of mercury and the iodides. It was incorrect, he said, to assert that mercury is useful only in the earlier stages, for it often produced the happiest results in tertiary syphilis, especially of the nervous system, after the iodides had been tried without avail. The mercurial treatment need not be interrupted unless the patient gives evidences of hydrargyrism. He preferred inunctions or injections, when practicable, to the exhibition of the drug by the mouth. The treatment should be continued for a year after all symptoms have disappeared, but even then it was not safe to pronounce the cure absolute. He advised a mercurial course extending over three or four months prior to the marriage of one who had had syphilis.

DR. LANGLEBERT, Jr., of Paris, said that the mercurial treatment should be begun only on the appearance of the

prodromes of the secondary stage (headache, fever, etc.), and should be continued during the entire eruptive period. He employed mercury only to combat the cutaneous and mucous manifestations of syphilis, and never gave it in the intervals of freedom, since he regarded the drug as powerless to prevent any of the secondary or tertiary phenomena, and of service only during the stage of evolution of these symptoms. The iodides, on the other hand, might be prescribed at any time, and were pre-eminently the remedy for chronic syphilis. The average duration of treatment by the iodides should be about three years, and it should be begun only after the first eruption of the secondary stage. The mixed treatment may be preferable during the first period of the tertiary manifestations, but a cure in this stage can be obtained only by the use of the iodides for a long period of time. Tonic remedies, such as arsenic, iron, quinine, and sulphur, are of great value, although of secondary importance in comparison with mercury and the iodides.

Dr. Leloir, of Lille, read a paper, prepared by himself and Dr. Tavernier, on

MERCURIAL INJECTIONS

in the treatment of syphilis. The authors had practised 1,573 injections during two years; the drugs employed being calomel, yellow oxide of mercury, and gray oil. Of these the calomel acted the most, and gray oil the least, effectively. The injections were of most service in the secondary cutaneous lesions; but were of little or no use in mucous patches. Tertiary lesions uniformly resisted their action, and could be controlled only by inunctions and by local mercurial treatment. The disadvantages of this method of treatment were so great that it could seldom be employed in private practice. The most important of the evil effects observed were: Local pain of considerable intensity, lasting sometimes from one to nine days, or longer; paresis of the lower extremities; headache and vertigo; slight mercurialism; and a painful, non-suppurating tumor at the site of the injection. One curious fact, that was several times observed, was an eruption of mucous patches occurring four or five days after an injection. The injections ought not to be used in cases of cerebral or spinal syphilis, and were serviceable only in those cases of cutaneous syphilis in which a rapid cure of the eruption is especially desired. Relapses were very common after treatment by injections.

Dr. Jullien, of Paris, had seen a number of cases of

DILATATION OF THE STOMACH IN TERTIARY SYPHILIS,

and he thought a knowledge of the existence of this trouble was of considerable importance, for he believed it might be the cause of many of the nervous symptoms commonly attributed directly to the action of the syphilitic poison. He advised that treatment be directed first to the dyspepsia in these cases, and said that oftentimes the headache, vertigo, and mental troubles, which were thought to be syphilitic in their nature, would then disappear. The dilatation might be caused, he thought, by the drugs employed, especially the iodides, and he therefore regarded these cases as specially suited to treatment by injections.

Dr. Diday, of Lyons, was opposed to a continuous course of treatment, and thought it better to give mercury only during the presence of symptoms, for it was at this time that the bacillus was most injurious in its effects, and also most accessible to the action of parasiticides. The advantages of employing antisyphilitic remedies in this manner the speaker summarized as follows: 1, More prompt curative effects are obtained; 2, it will not be necessary to give such large and harmful doses during a fresh outbreak as it would be had the remedy been taken continuously; 3, since the treatment is made to depend directly upon the symptoms, the latter are more carefully watched, and thus the physician obtains a better knowledge of his case than he would otherwise have; 4, not attributing any prophylactic power to the so-called specific remedies, the physician will have made no promises to the patient, and will therefore not be held responsible when fresh symptoms appear; 5, a certain period of freedom from all symptoms, while no remedies have been employed, gives the patient a greater confidence in the permanence of his cure than he would have had, had he been taking medicine continuously.

Dr. Schwimmer, of Budapest, was decidedly opposed to the plan advocated by Leloir, of waiting until unmistakable symptoms had developed before commencing treatment. Syphilis was like any other disease, in that it ought to be treated as soon as it was recognized, and it was bad practice to wait until it had acquired its full development before attacking it. The treatment should be varied, he said, according to the race and climate, and it was not reasonable to insist upon a rigid plan to be followed by everybody everywhere. He had never seen any evil results follow the injection of calomel. He had before recommended salicylate of mercury as preferable to the bichloride, and he took occasion to refer again to its superiority in the treatment of syphilis, though he did not think it was as active as calomel employed hypodermically. He had not had much success with the thymate of mercury which had been recently recommended.

Dr. Neumann, of Vienna, began treatment as soon as the first positive signs of the disease were manifest, and continued it uninterruptedly long after the secondary symptoms had disappeared. He preferred mercurial inunctions to injections.

Dr. Kaposi, of Vienna, was strongly opposed to injections, which he regarded as altogether unscientific. In the case of a woman who had died in his service from acute mercurial poisoning following two injections of gray oil, an examination showed that a large part of the mercury had not been absorbed. Thus, in a similar case, if symptoms of hydrargyrism appeared, it would be impossible to withdraw the mercury at once, since there would be a reservoir in the tissues at the sites of injection from which absorption would be continually taking place. The speaker preferred inunctions.

Dr. Schüster, of Aix-la-Chapelle, was opposed to the injection of insoluble salts of mercury, which had never given any good results in his hands.

Dr. Castello, of Madrid, began treatment immediately upon being sure of his diagnosis, and continued it for some time after the disappearance of all symptoms.

Dr. Rosolimos, of Athens, said that cases were occasionally met with in which mercury, administered in all the different ways, failed to produce any effect. In such cases injections were indicated. He believed that injections were more efficacious in preventing relapses than were other methods of treatment. Abscesses might be prevented by making the injections on the rounded parts of the back, and the pain in this region was also less marked.

Dr. Pétrini, of Bucharest, had lately made a pretty extensive trial of tannate of mercury, and had been pleased with its action. His plan was to begin treatment as soon as the diagnosis had been made, commencing with one and a half grain of tannate of mercury per diem, increasing it at the end of ten days to three grains, and continuing the treatment for twenty-five or thirty days. All his cases so treated had done well, stomatitis being but rarely met with.

Dr. Mauriac, of Paris, preferred to commence giving mercury by the mouth, reserving inunctions and injections for particular cases.

Dr. de Watraszewski, of Warsaw, was opposed to injections of mercurial salts, since they are apt to produce considerable irritation locally, and if introduced into the circulation may give rise to symptoms of acute poisoning, or may be followed by serious pulmonary trouble. In some experiments made upon cats, he found that either gray oil or the yellow oxide of mercury, when introduced into a vein, caused very extensive lobular hepatization, the trouble being most marked when the yellow oxide was used. The vaseline used to hold the mercurial in suspen-

sion had much to do with these evil effects, for when mucilage was employed as the menstruum the pulmonary troubles were much less marked. This was due to the fact that the mucilage mixed readily with the blood, while the vaseline did not, and was carried to the lungs holding suspended in it the mercury.

DR. DU CASTEL, of Paris, was opposed to mercurial injections, being unable to see that they possessed any special advantages over other methods of administering the drug, and fearing the effects upon the kidneys and brain of mercury introduced so directly into the circulation.

DR. BALZER, of Paris, had never seen any injurious effects from injections of mercurial salts, and believed that they were very useful in certain cases.

DR. BERTORELLI, of Milan, said that he often had recourse to calomel injections, and he had been surprised to hear so much said against this method of treatment. It was employed quite extensively in Italy.

DR. BARTHÉLEMY, of Paris, looked upon injections as most suitable in certain cases, especially in hospital practice, but it could be employed only exceptionally.

## NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, May 22, 1889.*

WILLIAM P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

DR. H. J. BOLDT presented a specimen of

### PERFORATION OF THE VERMIFORM APPENDIX.

The patient, nine years of age, had, according to the history given, always enjoyed good health until the night of May 6th. He was seen early on the 7th, complaining only of diarrhœa, and had some vomiting; no pain. Examination, however, showed tenderness and tumefaction in the right iliac fossa. The diagnosis of perityphlitis and typhlitis was made. Ice-bags were applied, proper diet ordered, etc. The child had done very well under treatment, and was thought to be out of danger, both temperature and pulse having reached a normal point by the 10th. About noon, though, the patient experienced a sudden pain, radiating over the whole abdomen. When seen several hours later he presented the characteristic picture of one suffering from perforative peritonitis, the diagnosis of which was made, and it was assumed that a perforation of the appendix took place at the time when the pain was felt. He then seemed in fair condition for operation, yet by the time that preparations for such were made, collapse was so marked that it was desisted from, and the patient died a few hours subsequently. The autopsy showed the peritonitis to be very recent, and the perforation to be due to fecal concretions. The portion of appendix in the vicinity of the perforation was gangrenous. The pelvis contained pus.

The interesting features are that apparently the case was progressing so very favorably, and that it sank so rapidly after occurrence of the perforation. Although the history did not elicit any previous symptoms, yet the speaker was confident that all these cases have had them, and they were left unnoticed. The majority of cases will go to a favorable termination, without operative interference, by proper treatment, consisting of rest, the ice-bag, and diet. Medication is seldom required; yet one should be on the alert, when having such a patient in charge, to be ready for operation should necessity require it.

Dr. Boldt had seen in the same patients several attacks of perityphlitis and typhlitis in the course of two years, and then finally a perforation of the appendix occur which terminated fatally. Such cases are not unusual.

DR. C. N. DOWD said that the case just related recalled one that he saw about a year ago in one of the house-staff of Roosevelt Hospital. He suffered for about three weeks from symptoms of intestinal trouble, and then signs of perityphlitis appeared. About a pint of pus was found in the pelvis, and there was complete perforation. The vermiform appendix was gangrenous, and the appearances presented were as though there had been a strangulation.

DR. VAN SANTVOORD said that Mr. Frederick Treves had found evidence of previous inflammation of the vermiform appendix in about one-third of the autopsies made by him. This would seem to show that many people have trouble in or near the vermiform appendix at some period of their lives.

THE PRESIDENT asked Dr. Boldt what premonitory symptoms he had observed.

DR. BOLDT replied that there were occasional attacks of pain lasting for four or five days, then passing away, and recurring at intervals of a few days. Constipation was also present.

DR. S. T. ARMSTRONG asked whether the experience of the members of the Society was in accord with that of Mr. Treves. He had had only two cases of perityphlitis in a hospital experience of eleven years, and it had been rare in his experience to find evidences at autopsy of past inflammation in the region of the vermiform appendix.

DR. H. P. LOOMIS said that during the last four years he had taken special note of the condition of the vermiform appendix in all autopsies made by him, and in only a very small proportion of cases had he found evidences of old trouble in that region.

THE PRESIDENT said that he had recently followed a case of perityphlitis in a very young patient. There was a tumor over the cæcum, which subsequently passed away. Pus was found on exploratory puncture. He was wondering whether they ought to be on the lookout for future trouble in this case.

### SUPPOSED ULCER OF THE BLADDER.

DR. ARMSTRONG presented a bladder, removed from the body of a man on whom suprapubic cystotomy had been performed in the early part of last September. The patient was admitted to hospital for hæmaturia following a gonorrhœa. An examination with the cystoscope showed what was supposed to be an ulcer in the wall of the bladder; but when the bladder was opened by the suprapubic operation the spot was found not to be an ulcer but simply a furrow in the mucous membrane. The hemorrhage came from the kidney.

Dr. Armstrong then presented a second specimen showing

### ANEURISM OF THE AORTA WITH EROSION OF THE TRACHEA.

The patient was admitted to the Marine Hospital with a diagnosis of Bright's disease and pulmonary tuberculosis. He had had pneumonia four years ago, and dated his present illness from that time. In March of this year he was suddenly seized with a violent hemorrhage, and died instantly. At the autopsy old pleuritic adhesions were found. Arising from the ascending portion of the arch of the aorta was a sac containing fibrin. It had produced ulceration of the trachea, but the opening had been completely closed by a clot. A subsequent erosion of the bronchus had caused the hemorrhage from which death resulted. The aneurism had not been diagnosticated during life. This was the second case of rupture of an aneurism which had occurred in the hospital within six months.

DR. L. H. SAYRE presented a portion of a child's tibia and some slides for microscopical examination showing the lesions of

### RAREFYING OSTEITIS.

The specimens were removed by operation from the leg of a child, nine years of age. The child was born of healthy parentage, at the seventh month. When three years of age the patient sustained a fracture of the right tibia, at the middle third, while he was being jumped on the floor. The fragments united at a sharp angle, and the bone was subsequently refractured, and an apparatus

making pressure over the seat of deformity was applied, which caused ulceration at this point. The child was brought to New York in order to have what was supposed to be a lateral twisting of the tibia straightened. Examination revealed an enlargement of the leg in which there was an obscure sense of fluctuation. An exploratory incision was made over this enlarged part, and the bone was found to be very much softened. A small piece was removed with a trephine and presented the appearance of a malignant growth. It was sent to a microscopist for examination, and the first report from him was that it was a giant-cell sarcoma; but just before the time set for operation he made another report saying that he was not certain of its malignant character. Dr. Sayre excised the tibia about ten days ago, and the child has done very well since the operation. The speaker was of the opinion that the case was one of osteomyelitis followed by rarefying osteitis. He asked that the specimens be referred to the Committee on Microscopy for examination.

Dr. Van Gieson, from this committee, subsequently reported that the specimens showed the lesions of rarefying osteitis.

Dr. Van Gieson then demonstrated a

MEYNERT'S BASAL SECTION OF THE BRAIN,

and also presented a card specimen of empyema, in which there was a heart-shaped

UNILOCULAR EMPYEMIC SAC,

weighing nine hundred and fifty grammes, filling the lower right pleural cavity.

Dr. Wm. P. Northrup presented a specimen illustrating

SCORBUTUS IN AN INFANT.

The patient was a female child, eighteen months of age. One month before death the right leg and knee became swollen and tender. Temperature was 101° F. After two days the symptoms disappeared.

Two weeks before death the child began to seem sick; her gums were swollen and blackened, and bled freely. Two days later her left eyelid became black and swollen —temperature still 101° F. One week before death her pulse became 160 per minute, respirations 50, temperature 103° F., and physical signs of pneumonia developed. At this time her right eyelid showed ecchymosis, and there was marked swelling of the left thigh. During the remaining days of life her passages became black and pasty; the child was very anæmic, failed rapidly under symptoms of pneumonia, and died. No other ecchymoses were seen, and no evidences of syphilis. Child was wet-nursed the first sixteen months of life, but on account of impaired nutrition was taken from the breast and was also given vegetable acids.

For a full description of the cases of which this is a typical example, see Eustace Smith's "Diseases of Children."

*Autopsy.*—Child well nourished. Left thigh symmetrically enlarged and larger than right, though both seemed disproportionately large. Left femur was normal at its upper extremity, epiphysis, and end of shaft; but the lower remaining portion was invested all about with a layer of black clotted blood, having a uniform thickness of 2 to 3 mm. This lay between the bone and its periosteum. The lower epiphysis was separated, and the end of the shaft eroded and softened. A similar dark layer, though less thick, separated the periosteum from the right femur. Right and left tibiæ were surrounded by a thin, dark, hemorrhagic zone beneath the periosteum, and the shafts of these bones at their upper ends and the lower end of the right femur were congested (as seen on section). The fibulæ and bones of the arms and forearms not affected. Brain was normal. Lungs: extensive pleuro-pneumonia of left side, lobar in character —lower and upper lobes; right, extensive bronchitis and scattered masses of hepatization. No hemorrhage in these organs, liver, spleen, nor kidneys.

Microscopic examination of the bone showed no syphilitic lesion to be present, and that the blood zone about the shaft was extravasation, without signs of active inflammation. There was softening and disintegration, but no suppuration in the cancellous bone-tissue. There was moderate congestion at the epiphyseal junctions; in one only was there softening and separation.

Dr. Northrup also presented a card specimen illustrating

DIPHTHERIA, GENERAL TUBERCULOSIS, AND PNEUMONIA.

At the autopsy the child was seen to be poorly nourished. Extensive and abundant pseudo-membrane from the tip of the nares to the beginning of the trachea, also in the œsophagus and stomach. Mediastinal and bronchial lymph-nodes very much enlarged, many cheesy, some diffluent, some containing discrete tubercles. Lungs thickly studded with discrete miliary tubercles; lower lobes consolidated, recent hepatization. Liver, spleen, kidneys, contained tubercles. Left kidney arrested in development, about one-fourth its normal size, its companion being correspondingly enlarged; ureter dilated. No obstruction found, and no lesion to account for the arrested development. Bladder normal.

Dr. Van Santvoord said that Dr. Northrup's case recalled one of his own, presented to the Society September 27, 1882. It was that of a helpless idiot, six years of age, in whom extensive hemorrhage, with separation of both upper epiphyses, had occurred under the periosteum of the upper halves of both humeri. This hemorrhage was apparently the immediate cause of death. The case was regarded by him at the time as probably traumatic. Reports that he had subsequently seen of extensive subperiosteal hemorrhage with epiphyseal separations had been regarded by their recorders as scorbutic. He had become convinced that his own case belonged under that heading. In Dr. Northrup's case the condition of the gums seemed conclusive as to the existence of scurvy.

Dr. G. C. Freeborn presented a specimen of

COLLOID CARCINOMA OF THE GLUTEAL REGION.

The patient, a woman, aged sixty-seven, was admitted to the New York Cancer Hospital, April 28, 1888, giving the following history: About five years ago she fell backward while alighting from a street-car, striking on her hip. No bones were broken. She was under treatment for ten weeks. Two years after the fall a tumor was removed from the region of the sacrum and pronounced sarcoma. Four weeks after the operation she was seized with severe pain over the site of the tumor, and shortly after she noticed that the tumor was growing again. At the time of her admission to the hospital a tumor was found in the left gluteal region. It extended from a point five inches posterior to the anterior inferior spine of the ilium, horizontally, eleven inches to the region of the sacrum. The upper border corresponded to a line on the level of the crest of the ilium, and measured, from above downward, twelve inches. There was an elastic feeling to the mass, especially in the posterior portion near the median line. The skin was adherent over the greater part of the tumor.

On June 20th it was noticed that the tumor was growing into the pelvic cavity.

On July 23d the tumor had extended to the right gluteal region, had encroached to a considerable extent on the pelvic cavity. From this time to December 14th, when the patient died, the tumor grew rapidly, both externally and internally.

*Autopsy.*—A large, irregular-shaped mass is found occupying the gluteal region; it extends from a point one and one-half inch above the crest of the ilium, downward, for a distance of twelve inches. On the left side it is even with the outer aspect of the thigh; on the right side it extends downward on the outer aspect of the thigh, as an irregular oval mass, as far as the middle third. Numerous

oval elevations of various sizes extend over the posterior surface of the tumor.

On section through the median line the cut surface measures 23 ctm. in the vertical diameter, and 15 ctm. in the anterio-posterior. The tumor is found to be made up of dense tissue in which numerous cyst-like cavities are found filled with a gelatinous material. All the bones of the sacrum up to the first vertebra are destroyed, though their outlines can be made out in the tumor mass. The rectum, uterus, and bladder are pushed well forward against the pubes. The inguinal lymph nodes on both sides are enlarged. No secondary deposits were found in any of the organs.

Microscopical examination shows the new-growth to be colloid carcinoma.

The Society then went into executive session.

## Correspondence.

### OUR PARIS LETTER.

(From our Special Correspondent.)

THE PREVENTION OF PHTHISIS—THE ACADEMY OF MEDICINE ON THE CONTAGIOUSNESS OF TUBERCULOSIS—THE DANGER OF MEAT AND MILK EXAGGERATED—EXTRA-UTERINE PREGNANCY—A FŒTUS IN THE ABDOMEN FOR THIRTY-THREE YEARS—FOUR CHILDREN AT A BIRTH.

PARIS, August 24, 1889.

DR. VILLEMIN lately submitted to the Academy of Medicine the instructions which were drawn up by the Standing Committee of the Congress for the Study of Tuberculosis. It will be remembered that these instructions were intended for the public, to enable it to know and be capable of protecting itself against the disease, which the report says claims more victims in towns, and even in certain rural districts, than any other disease. It is calculated that about fifteen thousand, or more than one-fourth of the annual mortality of Paris alone, is due to tuberculosis. Also, that tuberculosis is a parasitic disease, virulent, contagious, transmissible, caused by a microbe, the bacillus of Koch. This microbe penetrates into the organism by the digestive canal with food, by the air-passages with inspired air, by the skin and mucous membranes, following sores, punctures, wounds, and various kinds of ulceration. The parasite of tuberculosis may be met with in the milk, muscles, and blood of animals serving for the food of man. Raw or underdone meat and blood, being capable of containing the living germ of tuberculosis, should be prohibited. Milk, for the same reason, should only be consumed after being boiled. The germ of tuberculosis is also capable of transmission from the tuberculous to the healtny subject by sputa, pus, dried mucous discharges, and all objects laden with tuberculous dust. Measures should therefore be taken against the germs of the disease which would be capable of preventing the propagation of the latter. The above is only the summary of the document which was submitted to the Academy, but where it did not meet with much favor. It was severely criticised by Drs. Dujardin-Beaumetz, Germain Sée, Lancereaux, and others. Dr. Dujardin-Beaumetz believes that phthisis is very common in the provinces. He considers that milk is much less dangerous than it is said to be. For milk to give tuberculosis, it must have been drawn from cows the udders of which were diseased. Moreover, it must not be forgotten that experiments by inoculation with milk or meat are not comparable with the results of alimentation, as in the latter case the normal gastric juice destroys or profoundly alters the pathogenic bacilli. In any case, if he would accept the recommendation of the milk being boiled before use, he cannot admit the interdiction of the use of raw or underdone meat, which are veritable medicaments in many cases, and always form the basis of a tonic alimentation. Dr. Daremberg does not believe that meat could produce tuberculosis, as bacilli do not exist in the muscular tissue.

Dr. Lancereaux is of opinion that it would be more useful to instruct the public as to the simple rules of hygiene than to talk to them about the contagiousness of tuberculosis, which is still a mooted point, except perhaps in certain definite conditions; that it is inoculable there can be no doubt, but it certainly is not contagious or infectious as are measles, small-pox, etc. He, of course, approves of the burning of the sputa of tuberculous subjects, as, if allowed to become dry, particles floating in the air may be inhaled by other persons, which would render them tuberculous. Dr. Lancereaux insists upon avoiding all depressing influences, as they act as predisposing causes of the disease. The two most powerful factors of tuberculosis are alcohol and deficiency of pure air, for it has been ascertained that the bacillus of Koch cannot thrive in pure air nor in a sound organism. Of ten alcoholic subjects, eight die tuberculous, and the more crowded are the inhabitants within a given space, the greater become the number of phthisical subjects.

Owing to the idea of the excessive contagiousness of tuberculosis being spread among the public, the people have become so alarmed that they are beginning to look upon phthisical subjects as persons to be avoided, which, of course, must have a most disastrous effect upon the patient, as well as upon his relations and friends. This exclusion is quite unjustifiable, and would remind one of a return to the practices of the middle ages, for the air expired by phthisical subjects does not contain the bacillus of Koch, as shown by repeated experiments. Moreover, statistics have proved that persons in permanent contact with phthisical subjects are not more frequently tuberculous than others. In fact, it is only the sputa that may be considered dangerous, but as regards meat and milk, they should be left for what they are. In order to completely free them from the tuberculous principle, if they contain any, the temperature to which they must be subjected is not to ebullition, but to 110° C., and even to 180° C., which will simply lead to inanition. Dr. Sée considers that milk is only dangerous when it is drawn from cows affected with tuberculous mastitis. As for raw meat, it does not determine tuberculosis. For several years Dr. Sée has treated his chlorotic patients with raw meat, and he has never seen that this treatment has produced a single case of this malady. It would be regretable to suppress this therapeutic means, which renders immense service in the therapeutics of phthisis and other maladies. According to the learned professor, tuberculosis is, after all, not so contagious as it is represented to be, and that which is termed contagion among relations is more frequently heredity. He would, therefore, not simply propose, as other speakers have done, to modify considerably the instructions submitted to the Academy, but he would suppress the whole document, that is to say, he would have nothing published but simple rules of hygiene applicable to all persons, and thus combat the idea of contagion which has been so much exaggerated. He would recommend the strict observance of cleanliness, the destruction by fire, when this is possible, of the sputa of phthisical subjects, and to prepare for them good physiological food by the ordinary means of cooking. As Dr. Villemin's instructions have to be considerably modified, the Academy of Medicine has appointed a commission which is charged to propose new conclusions, which should be independent of the instructions previously submitted. This commission is composed of Drs. Cornil, Dujardin-Beaumetz, Germain Sée, Verneuil, and Villemin.

A medical man commenting on the subject of the above instructions expresses himself in the following pathetic manner: "Return, oh my masters, to a more normal appreciation of facts, and when you draw up rules of hygiene, quit for a moment your microscopes, which magnify everything, even dangers."

Professor Tarnier lately introduced to the Academy of

Medicine a patient who is the subject of an extra-uterine pregnancy dating as far back as 1856. At that period pregnancy had reached the full term, the beats of the fœtal heart were distinctly heard, but the medical man who was consulted on the occasion having diagnosed an extra-uterine pregnancy, decided upon practising laparotomy, but before undertaking the operation Dr. Paul Dubois, the celebrated accoucheur was consulted, and although symptoms of the death of the child had manifested themselves, he did not see the necessity for immediate intervention. In 1859 the patient had occasion to consult M. Nélaton, who, after having established the previous, diagnosis, refused to operate. Since that time this woman had been lost sight of, when, a short time ago, she consulted Dr. Tarnier, who, on examination found a tumor in the sub-umbilical region, evidently constituted by the presence of a child. This tumor was divided into two parts, corresponding with the head and trunk, which were distinctly felt. The patient is now sixty-six years of age, and is in the enjoyment of comparatively good health, as she suffers from nothing but a slight inconvenience from the size of the tumor. The abdomen is so flabby that the feet of the child are easily distinguished from the other parts of the body.

At a subsequent meeting Dr. Tarnier related the case of a woman who had just been delivered of four living children: the first weighed at birth 1,900 grammes; the second, 1,580 grammes; the third, 2,100 grammes, and the fourth, 1,580 grammes. She already had had twins at her first confinement, at her second she had only one. Her maternal grandfather was a twin-brother.

## ELECTRICAL RESISTANCE OF THE HUMAN BODY.

To the Editor of The Medical Record.

Sir: A layman ventures to ask the freedom of your columns in regard to the discussion on the subject of *thanatelectrisis*.

I have followed with some interest the different opinions advanced by medical men, in this discussion, as to the proper electrical resistance of the human body. Frankly, is not this question one that requires the experimental training and knowledge of the physicist rather than the knowledge and training of the physician? Commenting on a letter from Dr. Sachs, you state that "the methods of testing human resistance are not difficult or complicated, and neither Jolly nor Gärtner can be credited with any superior and exclusive knowledge of the technique which would enable them to obtain more certain results than have experienced electricians like Edison." I agree with that part of the statement relative to Jolly and Gärtner, but with reference to Mr. Edison (for whose genius in certain directions we all have a warm admiration) he certainly is not familiar with the methods and use of instruments of precision in electrical measurements, and he candidly describes his position as that of "inventor," and in a manly way acknowledges his unfamiliarity with electrical instruments of precision. The measurements of human resistance made at Orange are entitled to just about the same weight as the evidence on the certainty of death given by the experiments on animals at Orange, wherein those of the animals that did succumb (for some the experimenters were unable to kill) were all immediately dissected.

The statement that "the methods of testing human resistance are not difficult," should not, bearing as it will the weight of your authority, pass unchallenged. The matter of determining accurately the electrical resistance of a good many objects (among them the human body) is just so difficult that notwithstanding all the means at hand in the finest physical laboratories, these resistances are not yet determined with any degree of closeness. Maxwell, Helmholtz, Mascart, Joubert, Thomson, Von Webber, and Rayleigh tell us that electrical resistance is a velocity, a length divided by a time, and as such I have only to quote the pertinent words of Professor Anthony,[1] that "the velocity with which electricity passes over any given conductor is not known, and that velocity depends upon a thousand things." It may surprise some of your readers to learn that the old statements as to the velocity of electricity have all gone by the board—and the man who now compares the rate of transmission of nerve-sensation with the obsolescent 280,000 miles per second velocity of electricity compares something with nothing.

Furthermore, physicists do not measure all electrical resistances in the same way, *i.e.*, by a similar method. One who would take a foot-rule to measure the circumference of a circle would err less than the electrician who would undertake to measure with a Wheatstone bridge the resistance of the human body. There are many electrical resistances wherein the employment of a Wheatstone bridge gives unreliable results. The internal resistance of a battery (and this seems most fairly comparable with the human body, since it is among the possibilities that the heart possesses certain electrical properties[2]) is measured by the voltameter method; the insulation resistance of a cable and all very high resistances, by the balistic galvanometer and standard-cell method, etc.

Nor does the fundamental law of Ohm stand as the only law to be considered in determining human resistance. In all this discussion not a word has appeared as to the law of resistances in divided circuits, the very law that seems most applicable to the case, for the human body, in all probability, is a divided conductor, and in a divided conductor the joint resistance is the product of the separate resistances divided by the sum of these resistances—a very different quantity from the assumed simple resistance of a certain portion of the body, which may or not embrace the paths traversed by the current.

There are also heating effects, requiring careful determinations of current-strength, resistance, and time; but, without going further, it ought to be evident that the electrical resistance of the human body is a very complex problem to determine, and one in which only very discordant results can be obtained by the hasty application of primary formulæ. Very respectfully,

Alexander McAdie, M.A.,
Fellow Clark University, Worcester, Mass.

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 1 to September 7, 1889.*

By direction of the Secretary of War a board of medical officers, to consist of Colonel Edward P. Vallum, Surgeon; Major Henry McElderry, Surgeon; Major Washington Matthews, Surgeon; Captain James C. Merrill, Assistant Surgeon, is constituted to meet in New York City on the first day of October, 1889, or as soon thereafter as practicable, for the examination of Assistant Surgeons for promotion, and of candidates for admission into the Medical Corps of the Army. The board will be governed in its proceedings by such instructions as it may receive from the Surgeon-General. Par. 1, S. O. 203, A. G. O., September 2, 1889.

Janeway, John H., Major and Surgeon. With the approval of the Secretary of War, leave of absence granted, S. O. 52, July 29, 1889, Division of the Pacific, is extended two months. Par. 1, S. O. 206, A. G. O., September 5, 1889.

Cleary, F. J. A., Major and Surgeon. Leave of absence for two months, on surgeon's certificate of disability, is hereby granted. S. O. 59, Headquarters Division of the Pacific, San Francisco, Cal., August 27, 1889.

[1] Remarks at Meeting of Electric Light Association, August 14, 1889.
[2] See Electrical Properties of the Human Heart, by Dr. H. D. Waller, The Medical Record, November 3, 1888.

EWING, CHARLES B., Captain and Assistant Surgeon. Leave of absence for twenty-one days granted, to commence on or about September 21, 1889, provided that at that time the post-surgeon now on leave has returned to duty. Par. 5, S. O. 201, Headquarters Division of the Atlantic, Governor's Island, N. Y., September 4, 1889.

BANISTER, W. B., First Lieutenant and Assistant Surgeon. Leave of absence for fifteen days is granted. Par. 2, S. O. 82, Headquarters Department of Arizona, Los Angeles, Cal., August 23, 1889.

By G. O. 69, A. G. O., August 31, 1889, the garrisons of Fort Laramie, Wyo., Fort Hays, Kan., and Fort Lyon, Col., will be withdrawn, and the posts named will be abandoned as soon as it can be done with due regard to economy.

---

*Official List of Changes in the Medical Corps of the United States Navy for the week ending September 7, 1889.*

NASH, F. S., Passed Assistant Surgeon. Detached from the Dale and ordered to duty in the Bureau of Medicine and Surgery.

RUSSELL, A. C. H., Passed Assistant Surgeon. Ordered to Naval Hospital, Yokohama, per steamer of September 28th.

HALL, C. H. H., Passed Assistant Surgeon. Detached from Naval Hospital, Yokohama, on reporting of relief, and to return home.

WHITE, S. S., Assistant Surgeon. Detached from Naval Hospital, New York, and ordered to the Minnesota.

STONE, E. P., Assistant Surgeon. Detached from the Minnesota, and to wait orders.

BRYANT, P. H., Assistant Surgeon. Detached from the Ajax, and ordered to Naval Hospital, Norfolk, Va.

WENTWORTH, A. R., Assistant Surgeon. Detached from Naval Hospital, Norfolk, Va., and to wait orders.

---

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 7, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 62 | 15 |
| Scarlet fever | 28 | 3 |
| Cerebro-spinal meningitis | 1 | 2 |
| Measles | 9 | 2 |
| Diphtheria | 55 | 16 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

CANCER AND AGE IN ANIMALS.—An instructive monograph on tumors in the lower animals, by Dr. Plicque, appeared recently in the *Revue de Chirurgie*. Among the more interesting definite facts included in his paper are the subject of melanosis and the relation of cancer to age. Melanosis, so malignant in man, is far nearer the innocent type of tumor in animals, especially in the horse. A melanotic nodule on a spot subject to irritation by harness sometimes disappears when the harness is adjusted so as to rub the new-growth no longer. The phenomenon has even been observed after the growth has begun to ulcerate. Other tumors, especially sarcoma and carcinoma, are often more intensely malignant in animals, especially the horse, than in man. Animals protected by the resources of civilization, so as to live to an old age rarely, if ever, met with in nature, are especially subject to cancer. Indeed, Dr. Plicque finds distinct evidence that age is far more predisposing to cancer in beasts than in man. Bouley, a French veterinary authority of experience, believes, on the ground of long observation, that dogs are doomed to cancer if they live to old age and are not killed by some acute pulmonary or gastro-intestinal affection. The cat, often cherished and kept alive when old and miserable, is also very subject to cancer in age. Statistics show that cancer is far more frequent in the carnivora than in vegetable eaters. This statement, as Dr. Plicque is careful to explain, is liable to mislead the pathologist; indeed, it is a capital example of a statistical doctrine eminently calculated to deceive the thoughtless. For if we only note what animals are mentioned above in this paragraph, the truth will become apparent. Old cats and dogs, carnivorous animals, are kept alive through a somewhat misguided philanthropy, or rather zoophily. But an old horse is seldom favored in this doubtful way, and cattle are killed, or ought to be killed, when they are young and tender. The herbivora have little chance of living long enough to have cancer.—*The Lancet.*

THE following interesting account of how a boy was wounded in a very critical place, and the injury was shrewdly diagnosticated and wisely treated by a medical student, comes to us in the daily press. We suppress only names. "The boy, aged fourteen, had been fooling with another lad, aged about sixteen, who was chasing him with an open knife, and upon coming up with him, gave him a cut about six inches long by one and one-half inch deep, extending from a point opposite the upper portion of the sanctum, diagonally across the left ham, severing the glutacus maximus and exposing the glutacus minimus. Mr. ——, a student at —— Medical College, stitched the wound to the entire satisfaction of his father, who witnessed his labors. Fourteen stitches were found necessary to close the same."—*Boston Medical ana Surgical Journal.*

PIANOFORTE PRACTISING.—Professor Wätzoldt, the director of the Elisabethschule (a girls' school in Germany), has addressed a most serious warning to parents and guardians on one of the evils of the present system of teaching girls. It is on the subject of what Wagner has contemptuously called *Hammermusik*. The professor begins by pointing out that the terms "musician" and "pianoforte-player" are not at all convertible. Then he refers to the illogical conduct of so many parents, who, for the sake of their children's health, ask them to be excused certain subjects of the school course, while they encourage them in the most excessive exertions at the pianoforte. Now, there is no subject which, if taught seriously, makes such a demand upon the store of nervous energy of the body as instrumental music. The brain, the eye, and the hands are all exercised at once; hence the frequent injury to health in the case of girls who have not a strong constitution. The professor has collected some statistics which show that more than half the pupils are taught the pianoforte, and that after their tenth year they spend twice as much time daily at it as at their other home lessons. Many girls complain of feeling tired, absent-minded, fidgety, of headaches and sleeplessness; and these complaints grow worse as they grow older. In all cases where the parents could be prevailed upon to diminish the hours of pianoforte practice, or stop it altogether, a marked improvement in general health was the invariable result. Herr Wätzoldt, therefore, recommends (1) that pianoforte instruction should not begin until the age of twelve; (2) that only girls of sound health, and who show some talent for music, should be made to play.—*Science.*

DOCTOR: "You see, wifey dear, I have pulled my patient through, after all! A very critical case, I can tell you." "Yes, dear hubby; but then you are such an excellent physician! Ah! if I had only known you five years earlier, I feel certain my first husband—my poor Thomas—would have been saved!"—*Ex.*

### THE EARLY DIAGNOSIS OF EXTRA-UTERINE PREGNANCY.

BY J. M. BALDY, M.D.,

PHILADELPHIA, PA.

THE subject of early diagnosis in extra-uterine gestation is one of the utmost importance, and it is most necessary that everything which is known on the subject be put before the profession at large in as clear and concise a manner as is consistent with the facts in our possession. This is particularly so, as on our being able or not to make the diagnosis rests the treatment, in many cases, as far as electricity is concerned.

Of late years much has been written on this subject, *pro* and *con*. Among the most recent contributions is an article in the July number of the *American Journal of the Medical Sciences*, by Dr. J. C. Reeve. With many of the propositions set forth by this writer I cannot agree, and do not think the facts will uphold his statements. Many of his errors can only be explained by the following words quoted from his article: "I fully recognize the fact that a paper presented to an assemblage of practitioners should be based largely upon personal experience, and that doctrine should be illustrated, or theory enforced. by the recital of actual observations. I deplore, therefore, that I have not clinical experience to lay before you." I have been extremely fortunate in being able to study this subject from a personal clinical and pathological stand-point, and shall base my subsequent remarks on an experience of some fifteen or more cases, on which I have either operated, assisted others to operate, witnessed the operation, or examined the specimens shortly after death; in all these cases I have previously been familiar with the histories. In addition, I have seen a number of cases diagnosed, by competent observers, as extra-uterine pregnancies, when no pregnancy whatever existed. I shall try, as far as possible, to come up to the standard laid down by Dr. Reeve, and "doctrine shall be illustrated, and theory enforced, by the recital of actual observations."

I take the paper of Dr. Reeve as a basis for my own, simply because it well represents the opinions of those who advocate that the early diagnosis of extra-uterine pregnancy can, for the most part, always be made and made with ease. Such, for instance, is the opinion of Grandin, who states that "in this country the weight of opinion certainly is that tubal pregnancy may ordinarily be diagnosticated early, and of late years the number of instances where this has been done have greatly decreased." Also of Janvrin, who stated at the Washington meeting of the American Gynecological Society that the diagnosis of extra-uterine pregnancy was easier than that of normal pregnancy; and so with many others. My own experience, in addition to a careful study of the experience of others, as it has appeared in print, has convinced me that the following is the true position we must assume on this subject:

I. In a certain proportion of cases of extra-uterine pregnancy, in the early stages, the diagnosis is easy and unmistakable.

II. In a certain (quite large) proportion of cases sufficient symptoms are present to more than warrant a diagnosis of extra-uterine pregnancy, such a pregnancy not being present.

III. In a certain other proportion of cases the symptoms, until rupture has occurred, are entirely wanting, or of such a dubious character as to in nowise warrant such a diagnosis.

If these three propositions are correct, it is very apparent that the natural deductions to follow are, that the diagnosis of extra-uterine pregnancy in its early stages is of such a doubtful and problematic nature that we are justified in saying it cannot be made. By that I mean when we are most certain that such a pregnancy is present it may not be; it may be present when we least suspect it. In other words, the uncertainty is so great we can never be certain.

Reeve says: "The symptoms which have been detailed may be classified partly in reference to the order of their occurrence, but especially as to their diagnostic value, as follows:

"I. *Suggestive.—a.* The general and reflex symptoms of pregnancy, especially if the pregnancy had occurred after a considerable period of barrenness. *b.* Disordered menstruation, especially metrorrhagia, coincident with symptoms of pregnancy; gushes of blood, accompanied by severe pelvic pains. *c.* Severe pain in the pelvis; attacks of pelvic pain followed by tenderness in either iliac region, and other symptoms of pelvic inflammation.

"II. *Presumptive.—a.* The existence of a tumor; this tumor presenting the characteristics of a tense cyst, sensitive to touch, actively pulsating; steady and regular growth of the tumor to be observed. *b.* The os uteri patulous, the uterus displaced and empty.

"III. *Certain.—a.* Paroxysms of violent and overwhelming pain in the pelvis, with general symptoms of collapse. *b.* Expulsion of the decidua."

This classification of symptoms commonly associated with this disease in the early stages, although not complete, I am willing to accept, with the exception of "paroxysms of violent and overwhelming pain in the pelvis, with general symptoms of collapse." Such symptoms would put the case beyond the point of the present discussion. When the cyst has ruptured, no one will dispute that the diagnosis can, in the vast majority of instances, be made with certainty. These "violent and overwhelming paroxysms of pain, with general symptoms of collapse, always indicate rupture. This is so generally accepted as a fact that I shall not attempt to prove it by citing cases. With this exception, then, I am willing to allow Dr. Reeve's classification of symptoms to settle the question of the possibility of diagnosis before rupture or the extreme uncertainty of such diagnosis.

I wish to make this explanation of the cases I have seen. In every case there has been rupture more or less. Often this rupture consisted simply of a teaspoonful or so of black clots, and these were contained in the sac itself. They did not show themselves until the sac was either torn loose from its adhesions, or was ruptured in the manipulation. For all purposes of treatment, therefore, they were unruptured, and they are just such cases as are picked for the electrical treatment. They go incidentally to prove Mr. Tait's proposition, that the peculiar paroxysmal pains of ectopic gestation always mean more or less rupture. In every one of them pains had occurred.

To prove my first proposition, that the diagnosis is at times easy to make, I will mention a case in which I assisted Dr. Montgomery, of Philadelphia, to operate. The doctor asked me to assist him with a laparotomy for extra-

uterine pregnancy. The woman had general and reflex symptoms of pregnancy; she had disordered menstruation, after missing a period, having previously been regular; she had rather characteristic pains, and had been discharging blood from the vagina, together with shreds. The uterus was found enlarged, with soft cervix, and a tender pelvic mass to the side was plainly discernible. The operation only verified the diagnosis. The cyst was unruptured, but contained a small quantity of blood-clots in itself. The pregnancy was not more than seven or eight weeks old. With the exception of one other case, those cases I have seen, in which the diagnosis has been as plain as this, had either ruptured into the abdominal cavity, or into the broad ligament, and the diagnosis, in which I concurred, was made in these, for the most part, from the shock or collapse of the rupture. This was notably so in a case on which I witnessed Dr. Goodell operate, and in another one on which I operated myself.

My second proposition, that at times sufficient symptoms are present which not only justify a diagnosis of extra-uterine pregnancy, but compel such a diagnosis, is proven by the following cases:

Mrs. X——: General and reflex symptoms of pregnancy, such as swollen and painful breasts, containing milk; morning nausea; enlarging abdomen; frequent micturition; constipation, etc.; had missed a period or two; patient thought herself pregnant; had not been pregnant for some years; irregular bleeding for a week or two; colicky pains in abdomen; passage of blood and shreds per vagina. Examination showed a cystic tumor to one side of the uterus, painful to the touch. The patient was seen by Dr. J. Price and several other gentlemen, all concurring with me in the diagnosis of undoubted extra-uterine pregnancy. Several days afterward an operation disclosed an ovarian cyst as large as an orange.

Mrs. Z——: General and reflex signs of pregnancy almost as above; not pregnant for years; missed a period; profuse bleeding, with clots and shreds; severe pelvic pains of a colicky character. Examination disclosed a pelvic mass to the side of the uterus, evidently a distended tube. A diagnosis of extra-uterine pregnancy was made by Dr. Kyneth, several other gentlemen, and myself. Operation in a few days, by Dr. Penrose, disclosed pyosalpinx. Any one reading the brief history of these two cases must admit that the diagnosis was not only warranted, but demanded. They were both seen and diagnosed by gentlemen who have had considerable experience with this and other pelvic troubles, and who were perfectly familiar with the literature of the subject. The objection may be made, and in fact has been made, that the shreds which were discharged should have been carefully examined, and that the case should have been watched to see if the cyst grew in size. My objection to waiting is, that while we are watching and studying, the patient will suddenly go into collapse and die from a rupture before anything can be done for her. What we want is to make a diagnosis when we see the case, not to wait and run all the risks of the question being settled by death. Where the discharges can be, they should be examined. But often we do not see the shreds, only having the patient's word for their presence. Such was the case with Mrs. X——, and the woman was too sick to warrant any delay, especially as the rest of the history was so clear. The shreds, or "pieces of flesh," having been passed the day before, there being none present at the time of the examination, it was not deemed worth the risk of even one day's delay. Even had they been found, and the examination of them been negative, it would not have altered the diagnosis. The criticism advanced by Dr. Kelly, when the case of Mrs. X—— was reported, was that in a case of his own the cyst had diminished in size while under observation, and that this was a valuable symptom, and should be looked for. In his case the fœtus was dead and the liquor amnii had become absorbed. This would never occur while the fœtus lived, and therefore has nothing whatever to do with the question. Again, if the fœtus was dead, as the operation in his case proved it to be, according to our electrical friends, the operation was unjustifiable, for the reason that all was then accomplished which the most ardent electrician claims to aim at, viz., the death of the fœtus. I could go outside of my own experience and enlarge on this class of cases, if I wished; but my second proposition is sufficiently proven by what I have already given. A case I operated on only recently will prove my third proposition, viz., that at times an extra-uterine pregnancy is present and does not present sufficient symptoms to warrant a diagnosis.

Mrs. R——, came to me complaining of abdominal and pelvic pain. After giving a negative history, she was put on the table and a diagnosis of pyosalpinx was made, and an operation advised. One week later she sent for me, and I found her lying on her bed; she said she had been having abdominal pains all week; she arose from the bed in order to obtain a letter she had received from her husband. While on her feet she was seized with a colicky pain. As I watched her the idea suddenly seized me that possibly this might be extra-uterine pregnancy. I carefully examined her with this possibility in view. She had been bleeding off and on for over two weeks; the show was clear blood, with never a shred or clot in it; she had not the slightest general or reflex sign of pregnancy; her husband had been away for only three weeks or less, and she had not missed a period, nor had she had a scant one; she had been having children for the past six or eight years at regular intervals. The examination showed the uterus in good position, and the cervix perfectly normal for a multipara. There was a mass posterior, and apparently continuous with the cervix, so much so that had I not been able to clearly feel the fundus anterior, I should have thought it the fundus. The only symptoms, then, I had for diagnosis were the bleeding and the pain. These symptoms are such constant and almost invariable companions of all serious pelvic troubles, that without something more to sustain the diagnosis it had manifestly to be given up. Dr. Hamill made a most careful examination for me, and could find nothing more than I had on which to base a diagnosis; in fact, he did not think it a case of ectopic gestation at all. Before beginning the operation the next day, I remarked to the visitors that I was operating for what I had thought to be a pyosalpinx; that if it turned out to be a tubal pregnancy they must not say I had not at least suspected that possibility; that possibly I might find nothing but an intra-uterine pregnancy (the continuation of the softer mass posterior with the cervix making this a possibility). My preference for the diagnosis of pyosalpinx was because of the negative symptoms for extra-uterine pregnancy, and because the woman had been complaining of pelvic pains for the past three or four years; had pain at her menses; painful coition and defecation. She had been having more or less whites, and they had suddenly become profuse, with itching about the vulva, and painful micturition. She was in that state of life when one would expect her husband to infect her with gonorrhœa. Taking it all for all, the indications were clearly for pelvic inflammatory trouble, and against extra-uterine pregnancy. It turned out to be a pregnancy of the fimbriated end of the tube, with a small quantity (a drachm or two) of black clots in the cyst itself.

Now here is a case in which the diagnosis of ectopic gestation could not be reached, although a most careful examination was made with that possibility in view. These cases I present show some of the difficulties in the way of a correct diagnosis, even in the hands of those who are in the habit of seeing and handling such cases frequently. What is a difficulty in the hands of the specialist becomes oftentimes an impossibility in the hands of the general practitioner, and where one constantly used to dealing with pelvic and abdominal diseases may at times suspect or stumble into a correct diagnosis, those who have not the time to bear all these matters continually in mind, to the exclusion of almost everything else,

must very frequently fail. At any rate, from my own experience I show clearly how extremely uncertain the whole matter is, and what folly it is to say we can with any degree of certainty make the correct diagnosis Because in sooth we can in certain cases make the diagnosis and find it verified (for an unverified diagnosis is utterly worthless), what right have we, in the face of such an experience, to say it can always be made? If we admit that mistakes are and can be made, such as I have detailed, then the whole subject becomes at once one of great uncertainty, and my statement that the diagnosis cannot be relied upon becomes justified. That such is the true state of our present knowledge is proclaimed by the majority of those with any real experience on the subject, such, for instance, as Dr. Gaillard Thomas, who says, "Need I say how difficult such a diagnosis is at a period sufficiently early to prevent rupture of a distended Fallopian tube, which usually gives way before the fourth month of gestation has far advanced? Even after fœtal movements, the fœtal heart and the precious results of abdominal palpation put themselves at our disposal, accurate diagnosis is often far from easy. . . . There are few pelvic conditions which develop in the female, from phantom-tumor to fecal impaction, which I have not seen confounded with ectopic gestation." The advocates of the early diagnosis being drawn from the ranks of those who acknowledge they have only such knowledge as they obtain from the literature of the subject, or from those who make the diagnosis, treat the disease with electricity, but never verify it by either abdominal section or post-mortem examination. In other words, they only verify their diagnosis by the so-called "therapeutic test," which Dr. Reeve complains we, who differ from him in opinion, will not accept. In view of the great uncertainty in our way of diagnosis, as shown by my own experience, and verified by the knife, can any one blame us for not accepting such a test?

## INTUBATION IN CASES OF FOREIGN BODIES IN THE AIR-PASSAGES; WITH REMARKS CONCERNING FEEDING AFTER INTUBATION.

By S. J. MELTZER, M.D.,
NEW YORK.

W. G——, a boy, aged three years, while crying with his mouth filled with food, was suddenly seized with a choking spell. The mother, who was attracted by this circumstance, supposing that food had become lodged in the air-passage, turned the boy upon his head, slapped his back, and finally administered syr. ipecac in sufficient doses to provoke vomiting. The violent symptoms abated, and the boy is said to have slept peacefully the following night. In the morning, however, his voice appeared hoarse, and his breathing in the course of the day became more and more labored. I saw the child about 3 P.M., some twenty hours after the choking spell. The symptoms which presented themselves were those of a case of croup in a tolerably advanced state; and, indeed, without the preceding history I would certainly have diagnosed it as a case of croup. Having been unsuccessful in an attempt to relieve the child by the endolaryngeal method, I advised to consult a laryngologist. Upon my return, after the lapse of three hours, I met my colleague, who had also fruitlessly endeavored to relieve by the laryngoscopical method. He considered tracheotomy as the only means out of the difficulty. The child, however, had at once to be relieved, as its condition in the meanwhile became very critical. The child lay comatose, its face intensely cyanotic, pulse very feeble, frequent, and intermittent. The supraclavicular and sternal contractions increased to their utmost, and no air found access into the lungs. Many difficulties presented themselves to the immediate performance of tracheotomy; I therefore conceived the idea of trying intubation. With the assent of my colleagues present, I introduced an O'Dwyer's tube into the larynx, and relief thereupon followed. The child breathed freely, the pulse improved, the cyanosis disappeared—in short, the condition was nearly a normal one. I did not remove the tube, but so wrapped the child in a blanket that it could not free its hands and seize the thread. Small pieces of cracked ice were alone given to the child, and a constant watch upon the latter was ordered. The child passed a good night, the peaceful slumber being only now and then interrupted by coughing. Toward morning, however, the watching grandmother loosened the blanket, and fell asleep, whereupon the little patient, during a coughing spell, seized the thread and pulled the tube out. When I came I found the child breathing perfectly free, without any sign of stenosis or dyspnœa. Upon examining the tube I discovered that it was half-filled with viscid mucus, and that it contained, besides numerous small particles, a comparatively large, pointed piece of a nutshell. Although the larynx did not cause any trouble, a rise of temperature appeared the same day, which, as was soon proven, proceeded from a fibrinous pneumonia. The development and course of this illness was not of sufficient importance to be reported in detail. There first appeared symptoms of a pneumonic infiltration of the entire lower lobe on the posterior surface of the left lung. Five days later there also appeared a pneumonia of the right side, posteriorly and inferiorly, but not so extensive or severe as that of the left side. The temperature was moderate, but slightly above 102° F.; the general condition satisfactory, only a painful cough was present which reminded one of pleurisy. In fact, the dulness was so striking on the left side, even before the bronchial respiration appeared, that I, in spite of the origin, carefully looked out for the differential diagnostic symptoms of pleurisy and pneumonia before deciding upon the latter. Over the dull areas fine crepitant râles and vesicular breathing were present during the period before the appearance of the bronchial respiration; the areas of dulness remained unchanged in all positions. The dulness was not increased from above downward. The vocal fremitus was increased, that is, very pronounced, during the first few days, before the pneumonia invaded the right side. It is very probable that the infiltrated areas lay superficially. The fever disappeared two weeks after the beginning, and terminated by lysis. The dulness, which outlasted for a long time the bronchial respiration, disappeared gradually about three weeks later. Nothing remained; the child is perfectly well.

That we are here dealing with a foreign body in the larynx need not be further explained. The stenotic symptoms, however, did certainly not originate from a direct obstruction of the glottis by the foreign body—the latter was too small to cause this. It could, though, be conceived that there were other small particles present, which were coughed up and swallowed, and that the amount of these might indeed have occluded the glottis. In a direct occlusion, however, the first attack would not have passed off, and the second deciding attack would not have been developed relatively so slowly. It is much more probable that the first choking spell was produced by a spasm of the glottis, which was reflexly induced by the foreign body, whereas the subsequent gradually developing stenosis was occasioned either by a submucous swelling or by œdema of the glottis, which the irritation of the foreign body resting in the larynx might have provoked. We certainly find in literature mention of cases where foreign bodies remain for a long time in the larynx without causing any reaction. Still, these particles lay chiefly in a ventricle of Morgagni; whereas our piece of nutshell, by the nature of its pointed condition, might have been lodged near the edge of a vocal cord, where, on account of its frequent movements, the irritation must have been more frequent and intense.

The removal of the foreign body from the larynx can be explained in two ways; either that the body already in the larynx lay embedded in viscid mucus, thence by the introduction of the tube the body, with viscid mucus,

became adherent to the lower end of the tube, and was forced into the tube by coughing; or that in pushing the tube into the larynx the body fell down into the trachea, and upon coughing was forced up into the tube.

The origin of the pneumonia in our case cannot be attributed to the intubation. The tube remained relatively but a short time, and the child received nothing to drink while the tube was in the larynx. It is much more probable that the pneumonia originated from aspiration of very small particles during the choking; we certainly found a large number of these embedded in the mucus besides the larger piece.

As far as I can review the literature, the present attempt appears to be the first where intubation was performed for the treatment of foreign bodies in the air-passages. It is therefore appropriate to discuss how far intubation may be brought into play in the cases mentioned. Although this case terminated satisfactorily, it is yet apparent that this method will not only be of no avail in some cases, but will, on the other hand, work direct mischief in many cases. If, for example, the foreign bodies in the larynx be larger than the lumen of the tube appropriate for that particular case, then certainly intubation will be useless; it will, on the contrary, apparently do harm, as the body will be pushed from the larynx into the trachea, and the chance for the now expedient tracheotomy will be greatly impaired, as there is more prospect of success in tracheotomy to remove the foreign body when in the larynx than when it is in the trachea. I shall therefore attempt to state the conditions under which intubation in cases of foreign bodies in the air-passages appears permissible and advisable. Firstly, where we can with certainty assume that the foreign body lies in the trachea or in a bronchus. In this case there exists no contra-indication. In all these cases intubation should be performed and developments awaited. If the foreign body be smaller than the lumen of the tube, it will be dislodged by the severe coughing attacks always present, in addition to which the fluids which now and then flow down through the open tube may also be of service in facilitating its removal. If the foreign body be larger than the lumen, the success of tracheotomy will not in any respect be impaired if compelled to resort to it after the unsuccessful issue of intubation. In cases where the body dwells in the larynx the case is different. If the foreign body be sufficiently large to occlude the glottis, and the first choking attack do not pass off, then certainly tracheotomy should at once be preferred, if there only exists a possibility of performing it. If, for some cause, such a possibility be not present, then an attempt should be made to push the foreign body into the trachea by means of intubation. The trachea is much wider than the larynx, and what fills the former will allow the passage of air in the latter; besides, the tube lying in the larynx will prevent the foreign body from again becoming wedged in it, so that by the intubation a respite is gained for the possibility of a subsequent tracheotomy. In cases where the body does not occlude the larynx it is difficult to arrive at a conclusion. If the stenosis has assumed a dangerous aspect, and if it be for some reason not practical to perform tracheotomy at once, as in our case, then we ought unhesitatingly to intubate, and we may often avoid a subsequent tracheotomy, as the case above described shows. But if the case is not as yet very urgent, and tracheotomy can be performed with as great facility as intubation, then, in my opinion, it would be more rational to tracheotomize. If we certainly knew that the body could pass through the tube, then, in my judgment, intubation would certainly be indicated, with certain presumptions that the body would again be coughed out. But we have no hint of what size the foreign body may be, and it may possibly be larger than the lumen of the tube, though it is not large enough to obturate the rima glottidis. Should it be the case—should the body be larger than the lumen—then we still would not avoid tracheotomy; but then the latter presents a more favorable prognosis for the removal of the body if it be in the larynx than if it be in the trachea or fallen down into a bronchus.

To the cases mentioned I would like to add the further remark, that in a certain variety of foreign bodies in the air-passages intubation is unconditionally indicated, namely, where fluid deluges the lungs—the water, for instance, in drowned people, pus from a retropharyngeal abscess, blood in operations of the mouth, and especially the blood in pulmonary hemorrhages. Death in the latter cases mostly does not ensue from loss of blood, but from asphyxia, as the blood, which cannot escape rapidly enough, deluges the whole respiratory surface. Cases are cited in literature where tracheotomy under these circumstances was the means of saving life. I do not hesitate to state that in such cases intubation, to say the least, will prove of as great avail as tracheotomy. If we take notice what a large amount of fluid we may pour directly into the trachea after an intubation, without perceiving any threatening signs of asphyxia, we must conclude that the glottis alone is at fault if any fluid in the trachea can provoke asphyxia, inasmuch as the glottis is impelled to closure by the irritation of the fluid foreign body, and thus is the escape of this fluid prevented. At any rate we will not lose anything by intubating in such cases.

As an addition to the preceding communication, I desire to make a few remarks on a method of feeding after intubation. As is known, the question of how the child is to be fed, is, in the eyes of many, the weak point in the method of intubation, on account of the danger of "Schluckpneumonie." I have explained in another place[1] that the pneumonia can only be developed through active expiration while the glottis is closed. A mere aspiration cannot draw anything, even it be ever so small, into the alveolæ. If this theory be correct—and I hope soon to be able to experimentally demonstrate its correctness—we need not fear the "Schluckpneumonie" as long as the tube remains in the larynx and prevents the closure of the glottis; we must but cease with the feeding for some time before the removal of the tube, and cleanse the trachea with a mild antiseptic. But even without the fear of "Schluckpneumonie" the feeding after intubation is very difficult, because most of the food makes its way into the trachea, and but a small quantity into the œsophagus, and, furthermore, the children stubbornly resist taking food at all. To think of feeding by means of the œsophageal tube is in such cases the more natural, as this method of feeding has already come into vogue in ordinary cases of diphtheria.[2] But the introduction of the œsophageal tube through the mouth meets many difficulties and induces vomiting, which we certainly should try to avoid. Latterly, therefore, I have tried to overcome the difficulties by introducing a soft catheter (silk or rubber) into the stomach through the nose, and left there permanently. Though my experience in its use is limited to but two successful cases, I will briefly explain this method (which I could not find described anywhere in literature) so that others may try it. It gives promise of good results.

The outer end of the catheter was connected with rubber tubing, which was knotted so as to prevent the outflowing of the fluid from the stomach, and to retain it *in situ* it was fastened to the ear by a thread. The children, both otherwise stubborn, made no attempt to seize the tube. If nourishment was to be administered, a small funnel was attached to the tube; if the nourishment at times did not flow through, it was easily remedied by blowing into it a little. As food there was used milk, beef-tea, diluted wine, a little at a time, but frequently even during sleep; the child was never awakened by feeding. Ir to the mouth there was given only now and then a 1 to 10,000 solution of bichloride of mercury, in order to moisten the mouth, to induce cough, and to cleanse the trachea aseptically. Not a drop of this fluid entered

[1] S. J. Meltzer: Ueber die mechan. Verhältnisse bei der Entstehung der Pneumonie, Medicinische Monatshefte, 1889. Heft II.
[2] Renvers: Therap. Monatshefte, 1889. Heft III.

the œsophagus; no attempt at swallowing could be observed. If anything were injected into the empty nostril the fluid would emerge from the other one, in which the catheter was placed, so that the catheter is no obstacle in the treatment of nasal diphtheria. In one of the children the posterior nares were so completely occluded with diphtheritic masses that I was compelled to bore through the latter with a prostatic catheter before I could pass a soft catheter through the pharynx. Both children, of different families, had pronounced diphtheritic croup, all the members of both families had had diphtheria, and, in fact, several times, and among them there were types of a severe nature. One of the two children had pronounced croup twice within a short period and recovered. The other child died, but neither from croup, "Schluckpneumonie," nor anything connected with the intubation or method of feeding. It was a four-year-old rachitic boy, with a very severe septic nasal diphtheria, and an acute nephritis; he died of cardiac paralysis.

## VAGINAL TAMPONAGE.

By CHARLES C. FREDIGKÉ, M.D.,

CHICAGO, ILL.

Practising gynecologists have been and still are casting about for a means to support the uterus and its adnexa, by a ready, inexpensive, and practical process, the problem always having been how to do this in the absence of a fulcrum or *point d'appui*. To their constant exertions we owe the present elaborate process of tamponage. This process discards a fulcrum by taking advantage of elastic or resilient pressure, thus obtaining innumerable points of support, without doing violence to anyone.

After having employed absorbent cotton, oakum, jute, felt, etc., the writer thus far has obtained the best results by the use of pure lamb's-wool in loose felt-like sheets half an inch thick, manufactured by Messrs. Seabury & Johnson, of New York. This was formed into spindles of various lengths and thickness; disks, rectangular, square, wedge-shaped, and round and oval; cylinders, truncated cones, etc., wrapped with moist carbolized gauze, then loosely quilted and medicated as indications required. After having treated patients thus from one to four months, medication of these tampons could be dispensed with in many cases, the engorgement, pelvic pain, etc., being removed by this process, aided powerfully by the elastic abdominal supporter, transferring of the weight of all the undergarments from the hips to the shoulders, and restoring somewhat the natural security and tactile function of the foot by strenuously insisting on the wearing of laced shoes with low, broad heels and roomy across the toes. Considerable degrees of prolapse of the anterior and posterior vaginal walls were thus removed, and this in many cases of lacerations of the perinæum. During winter this process of tamponage need not be repeated more often than once a week, *i.e.*, in cases which by continued treatment have reached a purely mechanical stage, not complicated by any pronounced pathologic conditions; but during warm weather this will not do, for the process has to be repeated twice. Yet few have the patience, fewer the time, and still fewer the means to keep this up, and, since "possession is the death of love," therefore, after having ransacked the history of a process from gray antiquity to the present time, and mastered its principles and their practical application and execution, its endless routine repetition becomes a labor or task, for such patients then have practically passed out of the application of tamponage as understood at present, and a substitute becomes imperative—a substitute, not by a hard or semi-solid pessary, for his experience compels the writer to distinctly differ from the views of most practitioners, who look upon tamponage as an appropriate precursory procedure to the wearing of a pessary, but by a simplified continuance of the same process, at once efficient, inexpensive, clean, and of easy self-application.

It thus became a serious consideration to devise a tampon possessing the advantages of a pessary with few, if any, of its defects.

Comparative physiology teaches that the functions of what we please to call the perineal body are unknown. Civilization, which is not founded in nature, assigned to it the function of support, but this is not proven; for the apex of a cone or wedge cannot support anything, particularly when its base rests upon nothing, and comparative anatomy shows that the vaginal fornix is produced only by an intussusceptio cervicis uteri into the lumen of the vagina, induced by the assumption of the erect posture, which intussusception disappears nearly if not quite in the horizontal or genupectoral.

A cavity is thus produced which, if filled with plastic material, would result in the formation of a body corresponding in its general contour with that of a California pear, the anterior surface of which would be rather flat as compared with its more convex posterior and the small end of which would join the body under a slight obtuse angle.

In order, then, to permanently support this dome-like roof of that cavity, with its eccentric pendant of the cervix uteri and all other superimposed organs, the elastic and self-adjusting resiliency of a collapsable rubber pouch suggested itself.

Black sheet-rubber of the thickness of that employed in the manufacture of inflated ring-pessaries was cut into sections, according to patterns previously determined, having curvilinear edges, to bring out the shape of a pear, and united by welding and cementing over an expansible wire frame similar to that employed in Professor Otis' urethrometer, which was then withdrawn at the small end, when that too was united, closed, and perforated by a hole punched into it of one millimetre in diameter. The cemented edges of the sections form ribs which, when the air is pressed out of the balloon, exert a powerful tendency to expand. They, as well as the small end of the balloon, effectually prevent shifting when *in situ*.

Well lubricated with carbolized petrolatum, it is rolled up, and, according to previous instructions, the patient introduces it while in the dorsal decubitus, and when the small end is even with the orificio vaginæ the patient changes to the genupectoral without stepping on the floor.

The instrument is immediately drawn into the cavity, to which it seeks to adapt itself. The patient is then told to cough several times while maintaining this position during five to ten minutes.

There is next to no possibility of its changing position when once in place, by walking up or down stairs, stooping, lifting, reaching up, etc. A perfect fit is indicated when the patient, after having executed all these movements, cannot tell that she is aware of the presence of a foreign substance.

Active motion only tends to make it fit closer, by its constant inclination to adjust itself to the continuously changing lumen of the vaginal vault and ever-varying pressure by the organs superimposed.

The two thus far made were of necessity crude, expensive, lacking workmanlike finish, and devised tentatively for patients who were abundantly able and willing to pay. They more than met the requirements of these cases, having been worn constantly during the last five and three months.

The first was a case of retroflexion, complicated with displacement of the ovaries into the cul-de-sac of Douglas, laceration of the os and perinæum, and prolapse of the anterior and posterior vaginal walls, leucorrhœa, etc. Twice a week the vagina was douched with two gallons of hot water containing equal parts of sulphate of zinc and alum in solution (one teaspoonful to a quart), the lacerations of the os touched with liquid carbolic acid ninety-five per cent., the fornix dusted with equal parts of iodoform and tannin, a glycerinated, spindle-shaped,

quilted lamb's-wool tampon placed into it so as to form a horseshoe (patient in genupectoral and by means of a Sims'), followed by a wedge-shaped quilted disk, charged with powdered tannic acid, and a cylinder constricted in the middle, charged with pulvis zinci oxidi comp.

As long as congestion lasted the glycerites were used and changed every second week, such as the glycerite of ammonio-ferric alum, acetate of aluminium, sulphate of aluminium, of zinc, borax, acetate of lead, tannic acid, and boric acid in the form of boroglyceride of fifty per cent., prepared by melting eight troy ounces of boroglyceride (as prepared by the Merrell Chemical Co., of Cincinnati), and adding glycerine enough to make sixteen fluid ounces. The caustics to the os were also changed to iodized phenol, to conduct the granulation so as to prevent contraction and dipping in, the finishing touches being given with solid nitrate of silver—the disks and cylinders (strings were not attached to them) being also charged with the powders of these various agents according to indications; acute inflammation of the external parts, abrasions, etc., were relieved by the compound zinc powder prepared of

℞. Zinci oxidi puri..... ʒ vi.
Magnes. carb. pulv.,
Amyli pulv.....āā ʒ i.
Morph. sulph ..... ..... ..... ʒ i.
Misce bene.

Pure oxide of zinc possesses all the therapeutic properties here as well as subnitrate of bismuth, which is five times more expensive.

The function of the mucosa of the generative tract being mainly that of secretion, ointments were not employed; in fact, the writer has discarded them in the treatment of all cases, having relegated their use to the lubrication of the digits and instruments, the polish of which they prevent from tarnishing. When all these pathologic conditions were removed, exclusive of the laceratio perinæi, a soft-rubber stem, according to Professor A. R. Jackson, was introduced, followed by the collapsable rubber tampon, the diameter of the body of which was one centimetre larger than the cavity. It is removed once a week by the patient in the dorsal position, followed by a hot alum-zinc douche through a fountain-syringe. The patient has worn this now five months and enjoys perfect health.

The other case was that of a nullipara, twenty-nine years of age, married eight years, with hyperplasia of the uterus, chronic endometritis and cervicitis, ovaralgia, dysmenorrhœa, mennorrhagia, decided anteflexion, and constant pelvic pain. After dilatation of the neck, curetting, intra-uterine douches, iodized phenol, the cervix was kept patent by a soft-rubber stem (exchanged of late at the proper time for Dr. Outerbridge's cervix distentor to favor conception), the case went through the same routine treatment, modified as indications required, and now, after three months' constant treatment, is practically a changed person with a fair chance of increasing the population of the United States.

Its facility of self-application insures a longer period of constant support, which is not otherwise attainable, yet most indispensable in obtaining anything like permanence of relief. The significance of this no one can appreciate more than the practising gynecologist, who more often than any other sees his most elaborate efforts nullified and frustrated by the passive resistance of his patient.

It would be much improved by adequate facilities for construction, and the cost so reduced that those poor women who need them most could be supplied without charge at dispensaries, etc. The thickness of the material employed, the form, length and breadth of the instrument, its surface, length, width, thickness, number, shape, and disposition of its ribs could then be varied according to indications to be met. The ribs form a most integral part of it, which the intervening substance only serves to maintain in their relative position. They may be flat, fluted, little or not at all elevated above the surface, or they may stand out in relief, half-round, scrolled, ridged, tapering above and below, and disposed lengthwise, in a spiral, or horizontal. They act like so many continuous sutures in the tissue of the vaginal tract.

The inflated ring, the balloon and dumb-bell pessary inflatable by a tube, are cumbersome to apply, want adaptation, and are no improvement on the ancient hog's bladder.

Mechanical niceties, such as the lever, ball and socket, cradle, etc., as applied to pessaries, exist only in our imagination, but not when *in situ*; for, should they fit, they do so only by crude pressure, the difference of density of their substance as compared with that of the tissues being so great that they become foreign bodies, and as such not to be tolerated. They all presuppose but lack a fulcrum, and to however few their points of impingement may be reduced those points are not stationary. Indeed, such contrivances find no nidus in the canal of the pelvis, the diameters of anyone of the planes of which are not and cannot be constant. Clinical experience and observation teach that tamponage, even in its crudest manner, is far superior to the most elaborately constructed pessary. The prognostic importance attached to lacerations of the os and perinæum are shorn by it of much of their pathologic significance, and their surgical treatment becomes rather a matter of personal choice than necessity, except in cases complicated with vesico- or recto-vaginal fissures, degeneration, etc.

We thus obtain, while in the erect posture, to a considerable extent the benefits to the organs produced by the genupectoral, but be it repeated only then, when the corset on the thorax is pulled down so that its lower edge reaches midway between the crest of the ilium and the great trochanter, the buttons on the boots replaced by laces and the heels cut down, so that the centre of gravity of the body is restored and the security of footing increased by relieving the toes, which thus far have been lying cheek by jowl, like kittens in a basket; then, too, our boulevards will not be graced so often by the painful sight of ponderous dames waddling instead of walking for an outing, blowing like whales under the burden of an abdominal engorgement equivalent to an eight months' gestation.

445 Thirty-seventh Street.

## HEREDITY.

By J. T. SEARCY, M.D.,
TUSCALOOSA, ALA.

Certain modes of motion, or habits of action, are observable belonging to every grade of animal. The modes and habits always follow, in the life of the animal, a fixed line of sequence, and are peculiar to the species.

For convenience these habits of action can be divided into morphological and functional.

An animal begins, generally, from a minute genetic cell, and gradually develops into the size and form of the adult of the species. The primitive starting-point is the protoplasmic mass, which is called the nucleus of the cell. This material appears "specialized" to perform a certain routine of actions; or, it has the established habit of performing certain specific modes of motion. This is the connecting material between parent and offspring; or, it is the portion in the line of descent that breaks off from the parent, and has the habit of continuing previous ancestral habits. Its specialization consists in this.

The morphological changes are cellular, and consist in a proliferation and multiplication of new cells from the original genetic cell. In embryonic and fœtal life, these cells are seen to assume shape and form by aggregation. They collect in masses, some in one direction, some in another, constituting eventually the different structures and organs of the body. The growth of the animal follows in its specialized changes a method of development peculiar to the species. The morphological process ends soon in the development of a low grade of animal, but in one of

a high grade the development runs through a long chapter of changes, passing from a high to a higher complexity of structure. Morphological changes indicate a habit of action. There are also established modes of motion, or habits, in the functions of the several parts or organs. The organs, the communities of associated cells, in their aggregated capacity, exhibit also established methods; they indicate characteristic habits, always in accordance with ancestral modes. The morphology and the physiology of the animal, comparatively speaking, is habitual.

A number of years before the hypothesis of evolution was formulated to give an explanation to these methods of life, several observers, Agassiz among the first, drew attention to the fact that, in the embryonic and fœtal development of an animal of a high grade, its morphological and functional actions in their successive stages were analogous to the successive grades of lower animals. The new animal, in other words, beginning at the lowest cell-form, in more or less accurate detail, repeated the ascending scale of animal life. Such phenomena are matters of observation. No explanation was satisfactorily offered for them until the hypothesis of evolution was applied to them. This method of reasoning now permeates all science. No naturalist of to-day can avoid it. The study of physiology has to assume it.

Nothing is more simple, in explanation of the morphological and physiological habits of animals, than they are repetitions of previous methods of action, of ancestral modes. In other words, these habits of action have become fixed methods by reason of a long course of repetitions, extending, with occasional modifications, through ages of ancestral life. The occasional modifications of new adjustments are very few compared with the countless number of repetitions that have fixed the habits. This is the modern view of heredity. It may be defined to be the specialized property of the individual animal, beginning in the changes witnessed in the genetic cell and extending through those of its whole life, in which it repeats the modes of action of its ancestry. It does this morphologically and physiologically. Heredity, for short, is the habit of repetition.

Until recently the study of physiology has been very incomplete. It only devoted its observations to the individual. Science, in this particular, has made a very important and valuable "change of base." It now considers the actions of the living animal from a new stand-point. The individual is not now considered a separate agent distinct from others in the line, but is a part of the line of descent. In his lineal aspect he is not separate at all. There is no break in the continuance of his "matter in motion." The genetic cell, it is true, separates from the parent; but it is a segment, a portion of the lineal structure branching off. The material continuity is complete. Wherever the line breaks there is a complete cessation, which never resumes. The mystery now disappears. The physiological line of descent can now itself be considered as an individual and considered as a whole. A great deal of remodelling of philosophy has necessarily been done since this view has been taken of life.

At this point, an inspection of the methods of reproduction is interesting and tends to confirm these views.

The lowest and simplest method of reproduction is by segmentation, in which there is a simple partition of the parent into two or more parts.

A more complete method is by gemmation, in which the offspring begins as a bud from the body of the parent.

The method which is the habit of most advanced animals is by genetic cells, exceedingly minute compared with the size of the parent.

In essential particulars, these three methods are similar processes, and the last two may be regarded as modifications of the first.

In the reproduction of animals there are two other methods observable: one in which the parent animals are sexed; the other, in which they are not sexed.

In the non-sexed animals the offspring develops from a single genetic cell. In the sexed animals the offspring begins in the combination of two genetic cells.

A definition of the terms male and female among sexed animals is well stated, when we designate the male as the individual who has acquired the habit of not gestating his own genetic cells, but turns them over to the female to gestate in combination with her cells. The one does not gestate; the other does.

Inasmuch as there are lower forms that singly develop their genetic cells, we may suppose this was the original method.

Gestation is in some cases a very short process, and again, in many, the combination takes place outside the body of the female. But still, for convenience, this definition is good, as it applies to all the higher animals, the mammalia for instance; the female gestates, and the male does not. A better designation of the male is: he turns over his genetic cell for combination with that of the female. He most generally seeks the female for that purpose.

Offspring of sexed animals arise from a combination of genetic cells. The amalgamated cell is seen afterward to exhibit a combination of the habits of action of its two parental lines. There is a combination of substances and a combination of activities. Morphological and physiological habits appear combined. Genetic cells from widely separated species cannot combine successfully, because their habits of action are not alike. Only when varieties are nearly alike, the horse and the ass for instance, or the bison and the cow, can a successful combination be accomplished.

The most advanced species are so decidedly sexed, their genetic cells never develop singly. The habit of combination is too firmly established. There are, however, some lower species that are sexed, the honey-bee for instance, whose females do bear cells capable of single development.

In the human species there is no exception to these general rules. The same kinds of "habits of action" are observable. The offspring represents a combination of ancestral traits. The protoplasmic nuclei of the two genetic cells are seen to commingle, and the amalgamated cell follows a regular graded line of gradual development until the organs and form of the adult are reached, when we witness in all the modes of action a combination of the ancestral lines; we witness tendencies to repetition, unless diverted by unusual outside influences. It may not be an exact repetition of those of the immediate parent, but in atavism we witness the ancestral traits. The habit is repetition, unless diverted. This tendency shows itself in size, shape, color, complexion, features, in the modes of muscular motion, speech, voice, gait, and even in the most recently evolved traits of intelligence and character. The longest established habits are the most certain, those that in ancestral modes have been most frequently repeated, such as race or national characteristics.

Heredity, all through the animal kingdom, means the habit of repetition.

---

The Diuretic Action of Salicylic Acid.—Dr. Huber claims to have had clinical demonstration of the diuretic properties of salicylic acid. In twenty-five cases of rheumatism, he noted the quantitative augmentation of the urinary secretion after the administration of the acid. He found the quantity of urine to increase in the twenty-four hours from five hundred to seven hundred grammes. Similar results were noticed in cases of pleurisy. The diuretic dose of salicylic acid was about ten grains every three hours, till the quantity of forty-five grains per day was administered. The diuresis augments from the first day, and continues on the following days. Huber would not advise the employment of this remedy in typhoid fever, and still less in the course of nephritis; in fact, he would restrict its use to cases of simple pleuritic effusion.—*Gazette Hebdomadaire de Médecine.*

## MATERNAL IMPRESSIONS.

By J. WETHERBY, M.D.,

ARLINGTON, KAN.

"MINDS of great men do not run in the same channels." This seems to be true regarding maternal impressions, or "birth-marks," as they are commonly called among the laity. Although there is a great diversity of opinion in regard to this subject among members of the medical profession, it is generally believed by the people at large. Almost any grandmother with whom you may converse on this subject will relate instances that have come under her personal observation, that to her mind at least are undoubtedly birth-marks; and to tell her that you do not believe in such things as these would brand you forever as an ignoramus in that old lady's opinion.

The fact that the belief is so wide-spread, extending to all nations and peoples, civilized or barbarous, ignorant or educated, would of itself lead us to think that there must be something in it, some foundation for such belief. There are very few ideas which are almost universally accepted by the world, as is the belief in mother's marks, that do not have some pretty sure foundation upon which the superstructure is built. Of course there are many beliefs or theories that are merely superstitions, and many physicians relegate the theory of mother's marks to this class; but very often these same superstitions, which are looked upon as relics of the dark ages, are only perverted facts. Again, because our grandmothers universally believed in some theory it does not follow that their theory is correct, for it is often widely contrary to the truth; but the opinion of these old granddames is not always to be lightly set aside, for they are frequently close observers, and often arrive at very sensible conclusions.

The subject of maternal impressions has interested me very greatly of late, and I have watched the theories and arguments pro and con that have been advanced through the medium of our medical journals with both pleasure and profit.

Some doctors profess a disbelief in the theory because it cannot be scientifically proven; but were we to accept only that which is definitely and clearly understood, what a set of doubting Thomases we would be! The fact is that most things in nature are mysterious, if we would but admit it. We have our theories and many times are able to prove them, if not correctly, at least satisfactorily; but often after one has been proven and accepted, and regarded as a fixed fact, another rises up and demolishes our fair structure, while we gaze with doubt and wonder upon the ruins which the hand of progress and the fertility of man's brain have wrought. Even behind theories that have come to be regarded as fixed facts there often comes to our mind a *how* and *why* that the most elaborate theory does not reveal to us. Therefore we are forced to admit that there is in all nature, even in its most simple parts, a hidden something which no one except the all-wise Creator can ever fully understand.

In no field of science do the remarks just made apply with greater force than to the broad and ever-widening field of physiology. Ideas are constantly changing. Theories are advanced, accepted, and exploded. The theories of our grandfathers, who were educated men in their day, look, many of them, almost puerile to us; and our grandchildren will look back pityingly at the wisdom of the present generation.

Shall we, then, reject a theory or belief simply because we do not understand its why and wherefore? Shall we, like Thomas, disbelieve because we cannot see and behold? Again, will our disbelief alter facts? We know that many things are so, but why they are so we cannot tell; yet if the fact appeals directly to our senses, we are forced to believe it regardless of theory.

Then why should we, as physicians, believe there are no such things as birth-marks just because we cannot, or at least do not, understand their development or causation, or the relation of the cause to the effect? Physicians have said to me, "It certainly does look as if it might be a birth-mark; but since neither the child's vascular or nervous system is connected with that of the mother, I don't see how the impression could have been conveyed to the fœtus, and I think it is only a coincidence." Now, the question is not how does this come about, but does it come about at all?

In the affirmative we have such men as Rokitansky, Mitchell, Roth, E. Séguin, Foerster, Peacock, and many others; while many equally good authorities are found who are opposed to the theory. Byford, I think it is, says that a woman's occupation during her pregnancy will have an influence upon the mind of her offspring. On the other hand, a recent writer stated in an article upon this subject that the child in utero is no more under the influence of the mother's emotions than is an embryonic chick in the egg covered by the brooding hen. He did not state, however, whether there was any difference between the egg in the hen before the shell was formed and the egg in the nest, as regards its power of receiving impressions. There is absolutely no analogy in his comparison. Having said so much by way of introduction, I wish to report the following cases which have never been in print before, and which, to my mind, are genuine cases of maternal impressions.

Years ago, one of my aunts lay upon her death-bed, and the relatives were all assembled to bid her a last good-by. One of her aunts, who lived at a distance, did not arrive until just before my aunt died; and as she approached the bedside the dying woman recognized her voice and tried to greet her with a look of welcome, but so near to death was she that only the right eyelid obeyed the impulse of the will, the left remaining almost closed, which gave a peculiar expression to her countenance. It affected the visiting woman very greatly, and was frequently referred to by her for weeks afterward. At the time of the death-bed scene she was four months gone in pregnancy; and when, five months later, her child was born, there was the same degree of ptosis as was observed in the case of the dying woman, the same eye being affected. The eye was normal in every other respect.

Sceptics might say that the above case was only a coincidence, there being many cases of congenital ptosis; but what follows ought to convince the most sceptical, as two cases following each other so closely, in both of which there had been strong mental emotions of a certain character, would hardly be mere "coincidences." When the child just referred to was born, the mother recalled the effect which her niece's case had had upon her, and attributed the ptosis to it. It became the talk of the neighborhood, and everyone was anxious to see the child. Among the visitors was a distant relative of mine, who was also enceinte. She did not think of her own condition, and was surprised, when her son was born, to find exactly the same defect there was in the first child.

To my mind these cases prove that birth-marks are possible, and that they do occur. Both of the children have grown to manhood, and the ptosis is as marked today as it was when they were born. Neither woman expected her child to be marked.

Another case was that of a woman four months pregnant, who spent the day with a family where there was a child having convulsions, of which it died. Between the convulsions the muscles, especially those of the eyes, "twitched all the time," as she expressed it. She said the case seemed to fascinate her. Many times during the day she resolved not to look at the child again, and as often found herself watching it. When her child was born its eyes "kept rolling all the time, and all its movements were jerky."

A case reported by the writer in THE MEDICAL RECORD in 1888, was that of a woman who cared for some sheep during her pregnancy, and when her child was born its head was covered with a growth which seemed to be exactly like lamb's wool. She does not remember having been frightened by a sheep. The child is now four years of age and is

perfectly developed in all other respects. Her woolly head gives her a very peculiar appearance. There is no African blood in either of the child's parents. An interesting feature of the case is, that the wool never gets long enough to need cutting, and always falls out in the spring. I had some of the wool subjected to a microscopic examination, with the result that it showed the microscopic structure of hair; "but," the microscopist wrote me, "that does not interfere with the birth-mark theory, since the woman had no conception of the microscopic appearance of wool, and could only transmit to her offspring the impression as it was conveyed to her." Children are not marked with the *real* object, but with the resemblance of the object.

A woman who was pregnant, was watching at the bedside of her dying husband. Her left hand was held in his so tightly that it became painful. He died holding her hand in this manner, and when her child was born there were only the merest traces of rudimentary fingers upon its left hand. I do not know how far she was advanced in pregnancy when the impression was made.

A friend of the writer kept a fine stallion, and a pony stallion which he used as a "teaser." A fine thoroughbred mare, that had never been bred before, was covered by the stallion, and three weeks later was brought back to be tested as to whether she were with foal or not. Not wishing to excite the stallion that had covered her unless it were necessary, they used the "teaser," which she did not take, and at which she became very angry, biting and kicking at him viciously. In due time, and without being covered again, she foaled, and the colt was marked exactly like the teaser. There were no marks upon either the stallion or the mare, nor in their pedigree. The stallion got forty other colts that season, and none of the rest was marked in any way. Stock-breeders have come to recognize the fact of maternal impressions, and have done away with the use of an inferior horse as a "teaser."

Sometimes young mares are very difficult to get with foal the first time, and a jack, which is generally a sure getter, is used. Often the colts which are got by thoroughbred stallions from the same mares afterward, even to the third or fourth colt, bear strong characteristics of the mule. This is explained by breeders as being the result of the stronger excitement and greater impressibility of the young mare at the time of her being first covered.

I could cite numerous other instances that are better explained by the birth-mark theory than by any other, but they are not well enough authenticated to exclude doubt.

Although I cannot explain the theory of birth-mark, and do not attempt to, yet I am a firm believer in maternal impressions.

---

THE MODE OF ORIGIN OF HÆMOGLOBINURIA.—M. Lépine, in a recent communication, proposed the separation of cases of hæmoglobinuria into two classes, viz.: Those which depended on free hæmoglobin in the blood, and those of renal origin, depending on renal congestion and rupture of vessels in the kidney. If there was slight rupture of vessels in the glomeruli, and a few corpuscles escaped into the capsule of Bowman, these were broken up by the serous fluid which they found there, and their components were passed with the urine. He illustrated the possible local origin in the kidney without general ill-health by an experiment on a healthy dog. A cannula was introduced into each ureter, and one filled with sterilized water, the other with ammoniacal urine, the pressure in the two being equal. This condition was maintained for three hours, and then the urine drawn off with the cannulæ. That on the side of the water was normal, that on the other side contained abundant hæmoglobin, but no blood-corpuscles. Now, as ammoniacal urine preserves any corpuscles that enter it, the inference would be that the corpuscles in this case were not broken up in the general circulation, but immediately before entering the renal tubules.—*Lyon Médical.*

## AN OBSTETRICAL EYE-BANDAGE.

BY GEORGE E. ABBOTT, M.D.,

NEW YORK.

DURING the average confinement, at the end of the second stage of labor, while the accoucheur is busy tying the cord and afterward (with the assistance of the nurse) is attending to the safe and neat completion of the third stage, the baby is busily engaged in inoculating his eyes with cultures of vernix caseosa, etc., and often has such success that, like many another scientist, he, in due time, becomes blind to everything else, but by no means dumb.

To prevent this result I have of late practised as follows: As soon as the child is born, and while I am waiting for the pulsations in the cord to cease, I give the care of the uterus to the nurse and carefully cleanse the face of the baby with damp aseptic cloths, and place over the eyes a narrow bandage (about two inches wide and a yard long), also damp and aseptic, and secure it with a safety-pin, then cleanse the baby's hands, tie the cord, wrap the child in flannel, protected by a diaper, and let it care for itself with perfect safety, until the nurse is ready to wash it.

Thus far I have had no ophthalmia neonatorum.

Of course this will not prevent all ophthalmia, especially those catarrhal forms due to bright light, cold, smoke, dust, and gases, from ill ventilation; but by its use, those severe and distressing blennorrhœal forms of gonorrhœal, septic, and puerperal infection will, I believe, be largely prevented.

## CEREBRAL ABSCESS SUCCESSFULLY TREATED BY TREPHINING.

BY J. W. WRIGHT, M.D.,

BRIDGEPORT, CONN.

J. S——, aged forty-one, habits intemperate, was admitted to the Bridgeport Hospital, June 4, 1889, after having served a term of six weeks at the jail for assault. While there he had delirium tremens, and beat his head against the cell walls, producing multiple abscesses, for which he was brought to the hospital for treatment. The whole scalp was infiltrated with pus. Two openings already existed on the top of the head, and four more were made at the most dependent portions of the abscess cavity, two on the right and two on the left side of the head, and daily syringed with a $\frac{1}{2000}$ bichloride solution. Intense general headache followed the dressings, lasting for some hours. His temperature during the whole of his illness ranged from 98° to 100° F. The abscesses healed kindly, and the headaches became less severe. His skin was bronzed and eyeballs yellow. About July 6th he complained of a feeling of numbness and weakness in the right hand. On examination I found the right leg, arm, and face paretic. From this time he complained of a severe pain over the left parietal bone, at intervals. The paralysis continued about the same, and for short periods he was aphasic until July 18th. By this time the scalp abscesses had nearly healed, and the dressings had been removed. On this day he seemed more stupid, but answered intelligently when aroused. The following day he was in a comatose state, passing his fæces and urine incontinently; the pupils were contracted and irresponsive to light; the pulse was 48 to 50, and the respiration slow but regular.

On consultation it was thought best to operate, in the hope of finding an abscess in the region of the motor centre of the arm. On July 20th the head having been shaved, and the ordinary antiseptic precautions being taken, the fissure of Rolando was mapped out by the rules laid down by Lucas-Championnière, and a semilunar flap of the skin and periosteum reflected; an inch trephine was then applied over the spot previously indicated by a small drill hole through the skin, and the brain was exposed; the dura mater was now reflected, and an aspirating needle was thrust into the substance of the brain. No pus appearing the needle was withdrawn and reintroduced a little posterior and downward, when the barrel of the syringe filled with pus—two drachms. The blades of a dressing-forceps failing to find the cavity, a straight, narrow-bladed bistoury was introduced two inches, and the distal end of a soft rubber cathether inserted, through which eight drachms of pus were withdrawn and the cavity washed with water (which had been boiled) until it ran clear. The drainage-tube was left in, the flap stitched down, and the dressings applied.

The following day he pulled out the drainage-tube during the temporary absence of the nurse, and, holding it in his hand when she returned, asked "if he had done any harm?" Apparently not, for the wound has healed, the paresis is disappearing, and he is able to sit up, eats with a good relish and answers questions intelligently.

## PLACENTA PRÆVIA CENTRALIS.

By CHARLES E. WILLIAMS, M.D.,

HOULTON, ME.

Mrs. Z——, aged nineteen, pregnant for the first time, at eight months was seized with profuse hemorrhage on Sunday, August 4th. The hemorrhage continued with intervals of remission until Tuesday morning, when the physician who was in attendance asked for a consultation.

On my arrival I found the patient excessively weak from loss of blood, with blue lips, sighing respiration, a pulse of 120 and irregular. The bedding was soaked with blood and the vagina filled with clots. There was the baggy feel to the vaginal vault peculiar to placenta prævia, the os was dilated so as to admit a finger, and efforts at examination or movements of the patient excited flowing. Failing in my efforts to introduce a Barnes bag, I firmly tamponed the vagina and ordered stimulants and nourishment.

Leaving the patient in the hands of the attending physician, I left to visit other cases. Returning after five hours, I found that no hemorrhage had occurred. The patient was weaker, however, with a pulse of 130. Removing the tampon, I found the os dilated to the size of a half-dollar. I partly introduced the hand within the vagina and two fingers within the cervix, and making counter-pressure externally, I swept the fingers about the lower zone of the uterus, separating the placenta as I proceeded and causing some hemorrhage; working rapidly and crowding down the uterus with the left hand, I finally succeeded in reaching the placental edge on the right side. The distance reached by the fingers and subsequent examination of the placenta, convinced me that it was a case of central implantation.

Tearing through the bag of waters, the placenta retracted to the left and the head presented at the cervix. Administering a little ergot the case was left to nature, and in two hours I delivered the woman of a dead child.

Immediately after the birth of the child, the mother's pulse ran up to 160 and was hardly perceptible at the wrist. There was sighing respiration, apparent unconsciousness, and extreme faintness of the heart-sounds. The body became cold and the case seemed almost hopeless. Under hypodermics of brandy and external warmth, after two hours of steady work, she began to rally; the pulse grew stronger and fell to 132, and she broke out into a warm perspiration. From that time on she has made a slow but gradual recovery.

## PRIMARY SYNCHRONOUS TRIPLE AMPUTATION OF LEFT THIGH, RIGHT LEG, AND RIGHT ARM, FOR RAILROAD INJURY.

By W. W. WILLIAMS, M.D.,

WICHITA, KAN.

Johnny S——, four years of age. On the afternoon of May 3, 1889, I received telephone message to come to stock-yards at once, that a boy had been run over by the cars. On my arrival, I found the boy lying on the bed with right arm torn off just below the elbow, and lying near the bed. The right foot and ankle were crushed, and the left leg below the knee had both bones broken, and the flesh was crushed into a pulp almost to the ankle. The bleeding had been checked by pieces of cord tied around the limbs. I administered a hypodermic injection of morphine and atropine, also some whiskey. He soon rallied from the shock, and when reaction had taken place, my assistants, Drs. Purdy, Fabrigue, Fordice, and Van Nuys, of this city, having arrived, I amputated by the circular method in the following order: right arm, middle third; right leg, middle third; left thigh, middle third.

The boy was put to bed and surrounded with bottles of hot water; he rallied promptly from the anæsthetic, had a hypodermic injection of sulph. morphine and atropine at eleven o'clock at night, slept some, and took some milk through the night. At eight o'clock the next morning the temperature was 99° F.; pulse, 90. The boy had a ball in his hand, and said he could play ball anyway, and wanted milk. At twelve o'clock, noon, the temperature and pulse were the same. At 7 P.M. I received a telephone message to come at once, as the boy had a spasm, and they thought he was dying. Dr. K. F. Purdy and I arrived in a short time. The patient was then resting, with a pulse of 110, and temperature of 100° F. At nine o'clock the next morning, his temperature was 102° F.; pulse, 130. He could hardly be aroused, and continued in this state until four o'clock the following morning, when he expired. The dressings were not soiled, and were sweet and nice. No hemorrhage. I thought the prospect rather good the first twenty-four hours. The boy lived about sixty hours after the operation. I think he died from secondary shock or exhaustion. I only know of about six cases of recovery after injuries requiring synchronous triple amputations, and would like to know the mortality after such operations. I think if we would report our unsuccessful cases as well as the successful ones, we could soon have an idea as to what the mortality may be.

## VIPER-BITE TREATED BY ALCOHOL.

By JOHN B. HAWES, M.D.,

ASSISTANT SURGEON STEPHANS HOSPITAL, REICHENBERG, BOHEMIA.

In making my rounds of the wards on Sunday, the 7th of July, my attention was attracted by a priest administering the last sacrament to a youth. The religious ceremony being ended, I proceeded to examine the patient, a boy aged twelve, and found that twenty-four hours before, while gathering whortleberries, barefooted, he had been bitten by a viper in the toe. The marks of the fangs were plainly to be seen.

The boy was unconscious, pulseless, and cold. The leg swollen to the hip and quite blue. A faint and very rapid heart-beat, and a hurried and superficial respiration showed plainly the desperate condition of the patient. Hot claret and warm covering had been used against the collapsed condition, but the patient vomited the claret immediately. The doctors, who had been in consultation,

had informed the family that the boy must die, and at the time of my visit the father and brother were waiting in the corridor, expecting every moment to be informed that the end had come.

I ordered a bottle of fine cognac at once, and at four o'clock P.M., commenced giving teaspoonful doses of pure brandy by pouring it well back on the tongue every five minutes. Not until about six o'clock was any improvement to be noticed, although the brandy was retained. At this time, however, the pulse was to be felt, though it was very faint.

This treatment was kept up, increasing the intervals somewhat between the doses, until midnight, when the patient was conscious and the heart's action improving. After ordering tablespoonful doses of cognac to be given every half-hour during the night, I returned home.

The next morning the visiting doctors were astonished to find the boy not only alive but very drunk, the heart working beautifully. He had taken in this time about fifteen ounces of brandy. The leg had in the meantime been rubbed every half-hour with camphor-water, and its warmth and rosy spots here and there showed the renewed circulation. The brandy was discontinued and the external treatment kept up. Rubbing, however, caused much pain, as the limb was extremely tender. Owing to this fact, indeed, the patient could not be discharged until the 19th, twelve days after his admission, though he had entirely recovered from the effects of the bite, as well as of the brandy, by the fourth day.

The case has excited much interest here, and was published in the Vienna and Prague, as well as the local, journals, as a novelty; for, strange to say, the doctors here were not familiar with the cowboy method of treating snake-bites.

The interesting point in the case is that the alcohol produced its effect at so late a stage, and that it caused no vomiting.

## Progress of Medical Science.

PUERPERAL INFECTION AND ERYSIPELAS.—The infectiousness of puerperal fever was first formally asserted by Semmelweis, of Vienna, in 1849, but was not definitely established until Pasteur turned his attention to it, in 1879. He showed conclusively that a certain variety of micro-organism was invariably found in the tissues of women who had succumbed to this malady. This micro-organism, when injected beneath the skin of animals, gives rise either to septicæmia or pyæmia according to the method of cultivation employed, and thus the identity of the two forms of puerperal infection was demonstrated. The streptococcus found in the tissues of the victims of puerperal disease was noticed to present a well-marked resemblance to the micro-organism obtained from erysipelas, and clinical experience has long pointed to the existence of a relationship between these two diseases. Within the last three or four years M. Vidal has been enabled, by a series of elaborate and carefully conducted experiments, to show that the streptococcus of puerperal fever gives rise to erysipelas in animals, and produces the same clinical symptoms as the micro-organism obtained from ordinary erysipelas. A very important point which has been made clear is, that the same micro-organism may cause maladies which differ from each other very materially from a symptomatological point of view, according to the method of inoculation and the medium in which it multiplies.—*The Medical Press.*

TREPHINING OF THE PELVIS IN THE TREATMENT OF SUPPURATIVE PSOITIS.—Dr. Gangolphe, of Lyons, advocates trephining of the ilium in the treatment of suppurative inflammation of the psoas muscle. This affection is regarded as a very serious one, on account of the critical condition of the patient in the majority of such cases, of the extent of mischief, and of its possible extension to the hip-joint. Prompt release of the pus is the best means of preventing a fatal issue. If the surgeon be guided by the general practice, and wait until fluctuation be felt in the lumbar or inguino crural region, he will certainly find that the whole of the psoas muscle has then become disorganized, and possibly may favor by his delay perforation of the hip-joint and secondary arthritis, which complication invariably leads to a fatal issue. Dr. Gangolphe claims that the operation devised and performed by him presents no difficulty, and is free from danger. The ilium is perforated at a part three fingers' breadths below the highest point of the iliac crest, and five fingers' breadths from the antero superior spine. An incision about three inches in length having been made through the skin and fascia parallel to the course of the glutei, the fibres of these muscles are separated by director and finger. A second incision about two and a half inches in length having been made through the skin only, at right angles to the former, in order to allow free exposure of the ilium at the seat of operation, the periosteum is detached, and the whole thickness of the bone removed by gouge and mallet, so as to form an orifice of about the size of a two-franc piece. The situation of this orifice, the author has found by anatomical observations, corresponds in the horizontal decubitus of the subject to the most dependent part of the internal iliac fossa and also to the thinnest part of the ilium. Through this orifice the abscess cavity can be readily drained and washed out by injected fluids. This operation may be associated with the ordinary lumbar, inguino-crural, or even posterior-crural incisions, according to the circumstances, if the suppuration has extended into any of these regions.—*Revue de Chirurgie.*

THE CHOICE OF SUTURES IN ABDOMINAL SECTION AND THE CÆSAREAN OPERATION.—After carefully sterilizing samples of carbolized gut, chromic gut, silk, and silkworm gut, of similar thickness, Dr. Thomson made use of these materials in the following manner: Rabbits, cats, and dogs that had just given birth to young were selected, and an incision was made in the cornu of the uterus on each side, in each case. The incision was closed by suture, different material being used on opposite cornua. Sutures were also applied to the omentum and abdominal wound, in order to ascertain if they were there subjects to more or less rapid changes than the sutures in recently pregnant uterine tissue. No difference could, however, be detected in this respect. The animals subjected to experiment were killed at different intervals of time, the sutures being carefully inspected. The carbolized catgut sutures were found to be very thin in the subjects killed at the end of a week, and reduced to mere relics in the neighborhood of the knots at the end of ten days. Chromic gut remained absolutely unaltered, even at the termination of sixty-four days. The cut ends were more or less covered in by membrane. Silk ligatures were found loosened, yet entire, at the end of fourteen days. Nothing but scanty relics of this material remained at the end of sixty-four days. At the termination of the same period silkworm gut was found absolutely unchanged, the still sharp-cut ends of the sutures made of this material projecting freely into the peritoneal cavity. Dr. Thomson concludes that silk is the best and safest material for suture, particularly for the uterine wound in Cæsarean section. Chromic and silkworm gut, as well as silver, are bad materials, as they never undergo absorption; while, on the other hand, carbolized gut becomes absorbed too early.—*The London Medical Recorder.*

ONE DANGER IN THE TREATMENT OF OBESITY.—In a study of five cases of movable heart, Dr. Rumpf found that three of them were justly attributable to attempts to cure obesity.

TO ARREST HEMATEMESIS.—Hot water, as hot as can be drunk, is said to have been effectual in controlling several cases of gastric hemorrhage.

## THE DECAY OF OPHTHALMOLOGY.

DR. WILLIS VAN HOOK has been lifting up his voice in the *North American Practitioner*. He there asserts that ophthalmology is sinking into hieroglyphic decadence. Its records are no longer made in plain English, or even technical English, but are condensed and crumpled into cryptographic formulæ, or compressed into lurid lines of mystic, eye-straining, algebraic symbols. "There was a time," he writes, "when a general practitioner, of modest attainment, yet industrious withal, might learn a little about the eye. But now see to what an extent of endurance must the aspirant's patience be cultivated. For, besides being a littérateur, a mathematician, a physicist, a traveller, a linguist, a connoisseur in malt liquors, a mechanic, an after-dinner speaker, and, in a word, a true microcosm, the ideal ophthalmologist must have an accurate knowledge of such a perversion of typography as was never dreamed of by the scientific and philosophical Benjamin Franklin, the patron deity of the compositor.

"The 'literature' produced by these peculiarly educated beings looks as if afflicted by some dire eruption of which the pathology yet awaits elucidation. In the presence of this typographical eruption and the anticipated omniscient culture, the ordinary medical reader is pitifully lost in attempting to follow the vagaries of the ophthalmographer. For who, pray, but one inured to mental penance could comprehend the impetuous writer, carried on by a burst of impassioned eloquence through the exciting details of a case of ciliary spasm, when he concludes a glowing history with the statement that 'the spasm still exists, being equal to —25 D. ⊂ —0.75cy axis 75°?'

"These artificial and arbitrary hieroglyphics, thickly and increasingly scattered through ophthalmological literature, indicate a misdirected and mischievous energy, which, if not turned into more profitable lines of action, will completely exclude from a knowledge of this branch of our art that pariah of medicine, the general practitioner, unless he painfully and heroically masters its Volapük."

We sympathize with Dr. Van Hook, but we do not think he has completed his indictment.

There was a time when the ophthalmologist, before taking up his specialty, learned general medicine and surgery. He walked the hospitals, he studied pathology and physiology; he interested himself in the general welfare of the physician, and in the various economic and scientific questions which arose.

Now the "eye-man" jumps from a three years' course in a medical college to an eye-class in a dispensary, and in a few years is a full-fledged ophthalmologist. The specialty is thus being filled with men no doubt able and ingenious, but utterly narrow in their medical knowledge, and but little more in touch with the general line of medical work than is the dentist or the chiropodist.

## A WORD UPON THE REGULATION OF PROSTITUTION AND SEXUAL HYGIENE.

THERE are still a good many sanitarians to whom public health is a fetich before which they would sacrifice every other social or economic interest. Some of these enthusiasts would gladly serve the devil in order to reduce the mortality-rate. When individuals of this class have minds of a somewhat erotic tinge and have had perhaps some severe blennorrhagic experiences in their youth, they become intensely alarmed over the spread of syphilis and begin to advocate the regulation of prostitution.

To such persons we would strongly recommend a recent communication of Professor Aug. Forel, of Zurich, to the *Correspondenzblatt für Schweizer Aerzte*. Forel embodies in his article a report by Dr. Nicolsky upon the regulation of prostitution in Kiew. This report contains the result of a careful study concerning the extent and spread of syphilis and chancroid among prostitutes submitted to regular medical examinations during the years 1886 and 1887. It was found that, among the five hundred prostitutes of the city in question, about forty-three per cent. had syphilis or soft chancre, or both, there being six times more syphilis than soft chancre. In some houses the percentage of chancre and chancroid was sixty-six per cent., and there was found to be a yearly increase in these diseases among the controlled prostitutes. A committee of the Medical Society, under the direction of Professor Stukowenkof, made a further report upon the subject of prostitution and the spread of syphilis. They advocated the establishment of special hospitals and dispensaries for the venereal diseases, so as to secure prompt and efficient treatment of infected cases. They also recommended the instruction of the laity, by lectures and pamphlets, as to the dangers of syphilis. They condemned as ineffective all attempts to regulate prostitution by the State.

Professor Forel takes the above as a text for some very vigorous and sensible words regarding masturbation and prostitution. He, as an alienist, often met young neurasthenics and hypochrondriacs who had been prescribed fornication by their physicians. They had got some venereal disease, but had not been cured of their nervous troubles, for prostitution is no cure for onanism. There are, says Forel, several types of onanism. There is the imaginary masturbator, who thinks he has abused himself, but who in reality has rarely done so. These are usually hereditary psychopathic and hypochondriacal persons. Then there are persons with congenital sexual perversions, who masturbate often and in some outlandish way corresponding to their psychical abnormality. Again, there are those, and they are many, who are simply led on by example, and who stop as soon as they learn that it is unmanly and pernicious. Fourth, there are those who, through early sexual excitement or local irritation, are led to the habit; and finally, there are those, the so-called "nothonanisten," who have no opportunities for natural sexual indulgence.

Forel asserts that onanism, except in early age and in excess, is not seriously harmful. It should, of course, be severely condemned and stopped, and the health of the system allowed to depend upon nocturnal discharges. There are, he says, no psychoses resulting from chastity, but plenty that come from sexual excess and venereal disease. Professor Forel joins most heartily in the view of those physicians who, purely for physical and sanitary reasons, teach that continence is the wisest and safest course, and the surest preventive of venereal disease.

---

### ALCOHOLISM, CRIME, AND INSANITY.

THE time must soon come when the question of the proper method of dealing with the alcohol question will become one for statesmen, rather than, as now, for fanatics and politicians to consider. The facts and statistics recently brought out at the Congress of Alcoholism in Paris, illustrate this very well. One of the topics for discussion was the relation of alcoholism to crime. Everyone knows that excessive alcoholic indulgence leads to crime, but the attempt was made to show a direct relation between the two.

The following tables were given. In France the average amount of alcohol consumed *per capita* was in

| | |
|---|---|
| 1873-77 | 2.72 litres. |
| 1878-82 | 3.53 " |
| 1883-87 | 3.83 " |

The increase of crime was from 172,000 to 195,000; the increase of insanity from 37,000 to 52,000. In Belgium the figures were:

| | | | |
|---|---|---|---|
| 1851 | 138 litres beer, | 5 87 alcohol, | 2.00 wine. |
| 1871 | 159 " " | 7.66 " | 3.55 " |
| 1881 | 170 " " | 9.75 " | 3.75 " |

There was during this period almost a doubling in crime, suicide, and insanity.

In Italy a similar increase of alcoholism, crime, and insanity was shown.

In Norway, since 1844, the amount of alcohol consumed has gradually been reduced from ten litres per inhabitant to four litres (in 1876), with a corresponding decrease of crime.

The above figures are certainly very striking, and it is particularly instructive to learn that the decrease of crime and alcoholism in Norway has been due, not to prohibition, but to lessening the number of licenses, increasing the tax on spirits, and the temporary depression in business.

It will not do, however, to trace all the increase of crime and insanity to alcohol. In Bern, for example, where there are only 4 saloons to 1,000 inhabitants, crimes were more numerous than in Zurich, where the ratio is 12 to 1,000. Professor Vauderoy, of Liège, asserts that the increase of the tax on spirits in Belgium has had but a slight result; and Dr. Icovesco, of Roumania, asserted that in a district in his country where a large number of saloons were closed, alcoholism continued to increase.

Such exceptions must be borne in mind, but on the whole it seems to be quite certain that a high tax or license, and a reduction in the number of saloons and total amount of alcohol consumed, is followed by a diminution in crime.

The statistics of some of our own cities carry out this view.

### MEDICINAL USE OF HYDROGEN PEROXIDE.

IT is with pleasure that we peruse the new issue of *Squibb's Ephemeris* for July, 1889, confident as we are that whatever it tells us is in accord with the latest scientific advances, and is the result of careful thought and research. Among its articles is one by E. R. Squibb, on "Hydrogen Peroxide" (published also in *Gaillard's Medical Journal*, March, 1889). This substance, which is one of the most powerful, and at the same time the least harmful, of all antiseptics and disinfectants, has never come into general use, probably because it is so unhandy and spoils so readily (Dr. Squibb thinks it is because it is so little known and so little understood). It is made in large quantities by several large firms, but is used chiefly in the preparation of secret remedies. Its properties have been known for a long time. It is a compound of hydrogen and oxygen which is easily decomposed, yielding water and nascent oxygen which quickly oxidizes substances with which it is in contact. The mere application of a solution of peroxide of hydrogen to certain albuminoid substances is sufficient to liberate its oxygen, which immediately coagulates the albuminoid substance within its reach. Thus all sorts of virus, whether propagative or not, are destroyed or, by coagulation, rendered inert in its presence, just as when strong corrosive sublimate solutions are applied to them. The undiluted liquid peroxide is from its nature very unstable, and, on slight disturbance, breaks up into water and oxygen with almost explosive rapidity. Therefore, it is never made nor used undiluted, but is always dissolved in water. The "peroxide of hydrogen" which is furnished to the physician is really a solution of the pure liquid in water to which a little hydrochloric acid has been added, the acid being necessary to prevent rapid decomposition of the peroxide. A solution which will yield its own volume of active (nascent) oxygen is called a one-volume solution. The fifteen-volume solution (yielding fifteen times its volume of nascent oxygen) is that which is generally supplied by the makers. It is put up in pint bottles, containing about fifteen fluid ounces, sold at $9 a dozen. It is colorless and nearly odorless, tastes slightly acid, and leaves a slight, fleeting, not unpleasant after-impression. Changes in this solution are indicated by the formation of bubbles of gas, which rise through the liquid or adhere to the sides of the bottle, and also by increased pressure within the bottles. At or below 59° F. the solution does not change for a long time. At 68° F. it does change, sometimes very rapidly, giving off oxygen gas. The solutions, whether strong or dilute, should be kept cool, outside the window of the sick-room in winter, and on ice or in ice-water in summer. The bottles in which the solutions are contained must not be held in the hand for any considerable time, as its warmth will cause decomposition. It must not be kept in contact with metals, nor applied by means of metal apparatus, as it not only ruins the instruments, but forms poisonous salts from the metal. It does not attack hard rubber or glass. It is not necessary to apply it as strong as when it comes from the maker. The ordinary fifteen-volume solution sold is not injurious, but it is stronger than necessary, and to use it undiluted is wasteful. For the irrigation of a child's nostrils, pharynx, and mouth, a two-volume (made by adding two ounces of the fifteen-volume solution to a pint of water)

solution may be used every two or three hours, and any part of this solution passing into the stomach will do good rather than harm. Adults and children who can gargle—especially in scarlatina and diphtheria—may use, as a gargle and mouth-wash, a three-volume solution (three ounces of the fifteen-volume solution to a pint of water). For vaginal injections, as in cancer, etc., a thorough washing with the one-volume solution will often suffice, but it may be necessary to increase the strength until the desired effect is produced. When cloths wetted in a solution are laid upon external sores they should be covered with oiled silk. The methods for testing the activity of any solution are given in full, but need not be repeated here. Mr. Charles Marchand, of No. 10 West Fourth Street, New York City, is referred to as one of the best makers and furnishers of hydrogen peroxide. It is very necessary to get a good article, as careless preparation and after-handling may render it inactive. It is desirable that it should be applied very early when used in diphtheria, before the deposits in the throat have caused disease of the adjacent parts or of the general system.

---

### THERAPEUTIC WORK AT THE PARIS EXPOSITION.

AMONG the most interesting of the various world's congresses now being held in Paris, was that on therapeutics and materia medica. The occurrence of such a congress is itself a matter of note, for heretofore attempts to bring together medical men to discuss therapeutics alone have not been very successful, and therapeutical societies have always been failures. The work at Paris was to a considerable extent, however, directed toward the question of antiseptics and anti-microbian agents. One of the leading topics for discussion was that of "the antiseptics proper to each pathogenic microbe." M. C. Paul contributed the most important facts on this point. He gave tables showing first the minimum amount of substances sufficient to prevent putrefaction in a litre of beef-tea; the three most powerful agents were oxygenated water, corrosive sublimate, and nitrate of silver. The substances which most surely destroyed cultures of the typhoid fever bacillus were sublimate in proportions of 1 to 20,000, sulphate of quinine, 1 to 800, and carbolic acid, 2 to 200. In the subsequent discussion, M. Petrescii, of Bukharest, stated that, practically, in the treatment of typhoid fever, he had found sulphide of carbon (*sulfure de carbon*) and naphthol most effective, while M. Semmola recommended sulphur in doses of 1 to 20 grammes daily.

As to the tubercular bacillus, M. Paul gave the following list of substances which he said sterilized cultures completely: hydrofluosilicic acid, sal ammoniac (*ammoniaque*), fluosilicate of iron, or fluosilicate of soda, *polysulfure de potassium*, and silicate of soda. From this list it would look as though the silicate salts were especially antagonistic to the phthisical process. In the discussion upon this point M. Rueff gave an elaborate account of his method of treating phthisis by pulverizations of biniodide of mercury. He claimed that by it the patient received into the lungs, at each treatment, 3 milligrammes of biniodide, or sufficient to disinfect 80 grammes of sputum. M. Rueff's method has, however, been tried by others with very little success.

## News of the Week.

DENOUNCING A DOCTORS' TRUST.—The Farmers' Alliance of Georgia is reported to have adopted the following resolutions:

"*Whereas*, We have been informed that some of our physicians have gone into a combine, or organization equivalent to a combine, that is detrimental to our interests; therefore, be it

"*Resolved*, That we publicly denounce any such organization, and also any physician who has or may hereafter attach himself to that or any other similar organization; and we will not patronize any physician who belongs to that society when we can do better."

DARTMOUTH MEDICAL COLLEGE.—The plans for the Hitchcock Memorial Hospital, at Hanover, N. H., have been formally accepted. Work will be commenced in season to complete the foundations this fall. The structure will be of brick, with Portland-stone trimmings; about two hundred feet long, with accommodations for thirty patients. The estimated cost, exclusive of land, is $50,000.

RAILWAY CASUALTIES.—In a late issue of the New York *Railroad Gazette* is a report of the accidents which occurred in the month of May, 1888, and chronicles 145 as having happened in thirty-one days. In the catastrophes of importance enough to be mentioned there were 43 deaths and 158 injuries. The nature of the accidents is tabulated as follows:

| | |
|---|---|
| Rear collisions | 32 |
| Butting collisions | 27 |
| Crossing and others | 4 |
| Derailments | 75 |
| Unclassified | 7 |
| Total | 145 |

Passenger trains involved, 57.

This, we are told, is about an average month, and consequently the railway monster requires the sacrifice of about five hundred people yearly to satisfy his maw.

LONDON POST-GRADUATE COURSES.—After a good deal of discussion, a kind of post-graduate college has been established in London, by members of the medical staffs of Brompton Consumption Hospital, the Hospital for Sick Children, the Hospital for Paralyzed and Epileptic, the Moorfields Ophthalmic Hospital, and the Blackfriars Hospital for Diseases of the Skin. No names of teachers are mentioned in the advertisements.

QUADRUPLETS.—Dr. J. E. Shore reports the birth of four living children (*Omaha Clinic*). The mother is a woman of forty and the father is sixty-six.

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION meets next week (September 24th–26th), at Evansville, Ind.

A NEW DISEASE-GERM WANTED.—The Vermont Microscopical Association has offered a prize of $250 for the discovery of a new disease-germ. Information can be obtained of C. Smith Boyton, M.D., Secretary of the Association, Burlington, Vt.

PROGRESS OF MEDICAL EDUCATION.—The Iowa State Board of Health has decided that Iowa medical colleges

after 1891 must give a four years' course, if they desire their graduates to be admitted to practice within the borders of the Commonwealth.—*The Medical Age.*

BUT ONE MORE CONGRESS of interest to medical men is to be held in Paris this year, viz., the Congress of Hydrology and Climatology. This meets on October 3d, under the presidency of M. E. Renou. A Congress of Otology and Laryngology was held during the past week, under the direction of Dr. Duplay.

CARBONIC ACID IN PHTHISIS.—Dr. Hugo Weber describes a novel way of treating consumption, in the *Berlin. klin. Wochenschrift*, September 2, 1889. This consists in administering to the patient a teaspoonful of bicarbonate of soda before meals and following it with a glass of water containing twelve drops of muriatic acid. There is generated about half a pint (270 cc.) of $CO_2$, which is gradually absorbed and exhaled by the lungs. Weber reports nine cases in some detail favorably affected by this treatment.

DEATH FROM THE FAITH-CURE.—A young woman died in Brooklyn on September 12th of typhoid fever. She had been under charge of a faith-curer, and it is said persistently refused to summon a physician, in which refusal she was supported by others of her family. The coroner held an inquest and the jury brought in a verdict that the death was due to typhoid fever, hastened by criminal neglect on the part of the faith-curer, who was held for the grand jury.

THE BROWN-SÉQUARD INJECTIONS.—Dr. Alex. Szikszay has experimented with the Brown-Séquard testicular injections upon a number of aged Budapestians, whose returned vigor is celebrated in the *Pest. med.-chir. Presse*, and thence, via the medium of the daily press, throughout the land. Professor S. A. Rogers reports the results of injections in fifteen cases and states that they are "satisfactory" (*Memphis Journal of Medical Sciences*). Dr. Winslow Anderson reports the result of a careful trial on a single case, an old man of seventy, upon whom seven injections were made. The patient gained three pounds in thirteen days, temperature increased from subnormal to normal, muscular power slightly increased, constipation ceased; all of which, however, might easily have been the result of mental stimulus. A Detroit chemist claims to have found a stimulating substance in testicular juice, viz., "spermine."

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.—The next annual meeting of this Association will be held in Nashville, Tenn., November 12, 13, and 14, 1889. The following preliminary programme has been published: "The President's Annual Address," by Hunter McGuire, M.D., LL.D., Richmond, Va.; "Report of Gynecological Work, with Especial Reference to Methods," by R. B. Maury, M.D., Memphis, Tenn.; "Direct Herniotomy, with Cases," by W. O. Roberts, M.D., Louisville, Ky.; "Open Abdominal Treatment," by B. E. Hadra, M.D., Galveston, Tex.; "The Abortive Treatment of Acute Pelvic Inflammation," by Virgil O. Hardon, M.D., Atlanta, Ga.; "The Importance of Early Treatment of Inflammatory Affections of the Uterus," by William C. Dabney, University of Virginia; "The Relation of the Nerve System to Reparative Surgery," by Thomas O. Summers, M.D., Jacksonville, Fla.; "Concerning the Causes of Frequent Failure of Relief of Reflex Symptoms after Trachelorrhaphy," by W. F. Hyer, M.D., Meridian, Miss.; "Cranial Surgery," by DeSaussure Ford, M.D., Augusta, Ga.; "The Treatment of Ectopic Pregnancy," by W. H. Wathen, M.D., Louisville, Ky.; "Laparotomy in Extra-uterine Pregnancy," by Waldo Briggs, M.D., St. Louis, Mo.; "Epithelioma of the Penis, with the Report of a Case," by D. W. Yandell, M.D., Louisville, Ky.; "Laparotomy in Intestinal Obstruction," by C. Kollock, M.D., Cheraw, S. C.; "An Experimental Study of Intestinal Anastomosis," by John D. S. Davis, M.D., Birmingham, Ala.; "Operative Interference in Ascites," by Hugh M. Taylor, M.D., Richmond, Va.; "Observations Pertaining to Pregnancy and Parturition," by W. Duncan, M.D., Savannah, Ga.; "Puerperal Convulsions," by John Herbert Claiborne, M.D., Petersburg, Va.; "Some Remarks upon Aneurisms, Relating more Especially to their Surgical Treatment," by F. T. Meriwether, M.D., Asheville, N. C.; "Coccygodynia and its Treatment," by Hunter P. Cooper, M.D., Atlanta, Ga.; "The Improved Cæsarean Section *versus* Craniotomy," by W. D. Haggard, M.D., Nashville, Tenn.; "Conservative Surgery in Injuries of the Foot," by J. T. Wilson, M.D., Sherman, Tex.; "Gunshot Fractures of the Femur," by John Brownrigg, M.D., Columbus, Miss.; "Tropho-neurosis as a Factor in the Phenomena of Syphilis," by G. Frank Lydston, Chicago, Ill.; "Trophic Changes following Nerve Injury in Fractures, with a Report of Two Cases," by William Perrin Nicholson, M.D., Atlanta, Ga.; "Treatment of Malignant Diseases of the Rectum," by W. T. Briggs, M.D., Nashville, Tenn.; "The Achievements of Modern Surgery," by J. Ewing Mears, M.D., Philadelphia, Pa.; "The Treatment of the Pedicle in Suprapubic Hysterectomy," by William M. Polk, M.D., New York; "Abdominal Surgery," by Joseph Price, M.D., Philadelphia, Pa. Several other papers have been promised, the titles of which have not yet been announced.

DR. ERNEST LAPLACE, of New Orleans, has been elected to the Chair of Pathology in the Medico-Chirurgical College, Philadelphia. Dr. Samuel Wolfe, of Skippack, Pa., will fill the Chair of Physiology in the same institution for the coming year.

DR. GEORGE J. JANEWAY, of New Brunswick, N. J., died on Monday, the 16th inst., aged eighty-three. Dr. Janeway received his education at the University of Pennsylvania, graduating from its medical school in 1838. He then went to Paris, where he studied in the French schools and hospitals. He returned to New York the next year. In 1842 he moved to New Jersey, and five years later he became a physician in New Brunswick. He was mayor of the city one term—1869–71. Dr. Janeway had six children, among them being Dr. Edward G. Janeway, of this city.

THE ANNUAL MEETING OF THE AMERICAN RHINOLOGICAL ASSOCIATION will be postponed until October 9, 10, and 11, 1889, at which time it will be held at the Palmer House, Chicago, Ill.

THE first International Congress of Physiologists was opened at Basle, on September 10th, and sat for three days.

# Society Reports.

## BRITISH MEDICAL ASSOCIATION.

*Fifty-seventh Annual Meeting, held at Leeds, England, August 13, 14, 15, and 16, 1889.*

(Special Report for THE MEDICAL RECORD.)

(Continued from page 301.)

### SECTION OF MEDICINE.

THURSDAY, AUGUST 15TH—SECOND DAY.

DR. EDDISON, OF LEEDS, IN THE CHAIR.

DR. PAVY, of London, opened a debate on the

### PROGNOSIS OF ALBUMINURIA WITH SPECIAL REFERENCE TO LIFE INSURANCE.

The author of the paper said that the title of his paper had been chosen for him. The traditional view was that the presence of albumen in the urine was a reason for the instant rejection of candidates for life insurance. In former days, examination of the urine in patients had been less common and routine than it now was. Brinton and Sieveking dilated on the importance of examination of the urine in all cases presenting themselves for insurance policies. It had recently been found that albumen was present in many cases when it was not suspected, and the question had now been put, whether there might not be cases of albuminuria which might not cause the rejection of the applicant for such policies. Albuminuria sometimes occurred as a transient phenomenon. In forced exercise, such transient albuminuria occurred—for instance, in the case of the great pedestrian, Weston, who passed albumen in his urine after a walk of one hundred and fifty miles, which had greatly exhausted his powers. For a short time his urine was found to contain albumen and casts. Severe mental strain might produce transient albuminuria, as also might cold baths. When not transient, albuminuria might be grouped under three heads: when there was very little albumen, when a considerable quantity was found, and, lastly, when albuminuria was "cyclic," *i.e.*, existing only once in the twenty-four hours. A careful survey of all the collateral circumstances must be made. Bright's disease often was hereditary, or ran in families. Gout and lead-poisoning were likely to lead to some such affection. The other symptoms of the patient should be carefully attended to, such as any unusual pallor, impairment of vision, high arterial tension, want of appetite, or dislike to meat. The specific gravity of the urine would require attention, and a microscopic examination of it would be necessary in difficult cases. When casts in abundance were found in the urine such cases might be rejected as not fit candidates for insurance; on the other hand, absence of casts was not sufficient to show the patient to be a fit candidate. In some cases, in the male, casts of the seminal tubules and spermatozoa might be seen in the urine, which might be taken for casts of the tubules of the kidney, when no nephritis existed. Such were, in brief, the diagnostic marks of Bright's disease. In the first group, where only traces of albumen were found, it was not clear that kidney disease existed. Some tests for albumen were liable to objections because fallacious. The granular kidney was accompanied by very slight albuminuria. In the second group, where a certain amount of albumen existed constantly, it was probable that many such cases got perfectly well, and it was by no means invariably that the existence of nephritis could be detected in such cases, but a decidedly more than ordinary risk existed in these. As to the group of "cyclic" albuminuria, in many such cases there was no albumen found in the urine in the morning, but the amount increased during the day, and again, there might be none at night. As to admitting such cases as candidates for life policies, there was a certain amount of reserve to be made; although if they came as ordinary patients to the consultant, a greater degree of optimism as to the prognosis might be indulged in. Perhaps companies might come to admit such cases at a somewhat higher premium. The usual form of albumen met with in ordinary nephritis was serum albumen, but, in "cyclic" albuminuria, organic acids threw down a precipitate of mucin, and some serum albumen was precipitated by other mineral acids.

DR. MAGUIRE said that there were two groups of cases of albuminuria: the undoubtedly functional kind, and that not clearly functional. One great diagnostic symptom in this matter was the state of the pulse, and here the finger showed more than the sphygmograph. In cases of hereditary albuminuria there was a pulse of high tension. In cases where there was albuminuria only in the middle of the day and not in the morning, the pulse was that of low arterial tension. Albumen in such cases might be found in considerable quantities when exercise was taken. Hyaline casts were no signs of decided Bright's disease. Dr. Broadbent had shown that there was often low arterial tension in such cases, and the health was not seriously affected. The tension was never so high in similar cases as it was in true Bright's disease; and, three years ago, he had shown that the albumen present in such cases was not that of the organic disease, the presence of globuline alone indicated a less serious form of disease. But the kind of albumen present was not always diagnostic of the nature of the disease. The patients with high tension pulse should not be accepted as candidates for life insurance, whereas in the former group they might, he thought, occasionally be accepted.

DR. PYE-SMITH said that there were cases where acetic acid would cause a precipitate of mucin. The presence of globuline in urine was of less importance, and in such cases there might be no Bright's disease present. But in so far as a man passed albumen in his urine, he could not be considered to be in a healthy, but in a diseased, condition. Even when casts are found in the urine, this was not a certain indication of Bright's disease. In mitral disease, casts might be found in the urine without there being any nephritis present. While Bright's disease might occur without casts, it might also exist with them, and Dr. Mahommed had correctly said that Bright's disease might be present although there was no albumen to be found in the urine. With regard to albuminuria, its presence should be considered, as hæmoptysis, a dangerous symptom. When albumen was found in the urine we were entitled to indulge in hopes that it might not prove of fatal prognosis, but it was advisable to remain in that position and not to be risky in prognosis. In the case of a private patient, he might be encouraged to take a cheerful view; but, as officers of life insurance companies, he held that it was difficult to distinguish between accidental and permanent albuminuria. Lastly, as to the tests, it was surely very important that when persons were comparing different cases of albuminuria, they should agree to use the same test, otherwise much confusion was inevitable.

PROFESSOR GAIRDNER, of Glasgow, said that for many years past he had been studying the question of albuminuria as adviser to life insurance companies, and he was still uncertain as to the existence of anything that could correctly be styled physiological albuminuria. The word functional was not objectionable; but physiological albuminuria was not allowable. When Weston passed albumen in his urine when greatly fatigued, this could not be called a physiological symptom, any more than if, in similar cases, he had had an attack of bleeding from the nostrils. As medical officer to companies, he considered always that the occurrence of albuminuria was a danger signal. As to the practical testing of urine, he considered that the old test, heat and nitric acid, should be stuck to. He had found that among the middle classes who applied for insurance policies, the occurrence of albuminuria was far rarer than recent writings might lead one to expect. Indeed, such a symptom was decidedly uncommon in appli-

cants at his offices. If albumen were found to be present, the medical adviser should ask to have plenty of time to make up his mind; and a good plan in such cases was to ascertain who was the ordinary medical adviser of the patient, and to communicate with him and ascertain what the history of the case had been, as far as it had come under his notice.

DR. RABAGLIATE, of Bradford, said that where there was a mere trace of albumen, the prognosis might be considered to be good in albuminuria, and if the urine was of specific gravity 1.020 or upward; but where it was 1.010, it indicated an advanced state of degeneration of the kidney. The presence or absence of casts was of importance in the prognosis, and the concomitance of gout, eczema, or anorexia, were important guiding marks. The amount of oxyluria also should be considered in coming to a conclusion. Supposing that a person with albumen in his urine were admitted as candidate for life insurance, what amount of premium should he pay? Dr. Saundby's statistics showed that a very small number of persons died yearly from urinary disease; and he, Dr. Rabagliate, had taken the statistics of the Scottish Widows Fund, and found that eight per cent. of the deaths in that company were due to such diseases, and half of these were due to Bright's disease. He had also done his best to get the statistics of death from such disease at Bradford, and had found that about 3.4 per cent. of adult males died from Bright's disease in that city.

DR. DRYSDALE, of London, said he thought it useless to complicate the question of prognosis in albuminuria with business transactions. It was quite difficult enough without importing that element. The main fact now ascertained was that, whereas, when Dr. Bright wrote his work on "Albuminuria," the prognosis of all cases of albuminuria was for many years looked upon as almost, if not quite, fatal, but it was now known that hosts of cases of albuminuria got quite well, and lived for an indefinite number of years, and apparently without any deterioration of the health. If treated simply and without heroic drug medication, too, even apparently hopeless cases of albuminuria recovered. All this, however, gave but little countenance to the idea that even occasional attacks of albumen in the urine need be considered as of little importance. He could not help regarding the presence of albumen in the urine of any person as a dangerous symptom in all cases, just as attacks of hæmoptysis were always disquieting; and, for his own part, he thought that a person who had habitually or intermittently albuminuria should make his will, if he had any property to leave, and be prepared for any sudden illness, which might, of course, be avoided by careful diet and hygiene. His experience was that heat and nitric acid were the most practical tests for albumen, and he thought it a mistake to import such tests as acetic acid.

DR. CRANSTON CHARLES had found albumen in the urine of thirty-three per cent. of men examined between the ages of eighteen and twenty-four; and in the case of students going up for examination he had found traces of it in twenty-seven per cent. of the cases he had examined. Anxiety might cause the presence of albumen in the urine. In the case of a young lady, a patient of his, albumen was found in the urine; it was found that she laced herself too tightly, and when this was abandoned she lost the albuminuria. Prolonged muscular exercise caused also the presence of albumen in the urine. In some cases he had examined, so long as arterial tension continued high there was no albumen found. Peptones, serum albumen, and globuline might be present in such cases. The tests he made use of were cold nitric acid and picric acid.

DR. SAUNDBY, of Birmingham, said Dr. Drysdale had remarked that albuminuria was once considered a necessarily fatal symptom, and this was the real cause of the present discussion. The discussion on heart disease at Brighton had done great service in clearing up the prognosis of that disease, and so would this debate. There were many exceptions to the rule that albumen in the urine was to be looked on as of fatal prognosis. In some cases albuminuria was innocent, and Dr. Pavy's cases of "cyclical" albuminuria were examples of this. There were some cases which might be styled "mechanical" albuminuria. When the patients stood up there was albumen in the urine, which disappeared when they lay down or were sitting. Insurance companies might safely accept such cases; but at present it was necessary to be careful in advising them to do so. Gout, hereditary transmission, frequent recurrent micturition, were evil points in the prognosis of cases of albuminuria. If the urine deposited casts in great quantity this was of bad prognosis. A medical man examining for insurance companies had not time enough for accurate judgment. Dr. Pollock's work, recently published, was too optimistic in its prognosis of albuminuria; and, on the other hand, Professor Frank, of Edinburgh, was too timid in his recommendations. Cases presenting themselves with albuminuria to insurance companies should be asked to return in six months. Uniformity of tests should be insisted upon. He thought that Dr. Rabaglia's statistics were below the average, and it was known that there were less deaths from Bright's disease in Yorkshire than in other English counties.

DR. TYSON, of Folkestone, thought the best test for albuminuria was heat and nitric acid. There had recently been great apprehension in the public mind concerning the occurrence of albumen in the urine. There had been, indeed, quite a panic among a certain number of persons where there was no real cause for it. He, himself, had found albumen in his urine for nine months, and had got quite free from it, and from all disquieting symptoms. Deaths from Bright's disease were comparatively rare. He was not at all unwell when he had had albuminuria; and he had had several similar cases where his patients had been frightened by being told that they had albuminuria, although otherwise in excellent health. In such cases it was better for the patients to give up all attention to their urine. As to the prognosis in albuminuria, he admitted that it was to the older members of the profession that we must apply for information on such subject, for cases must be watched for many years before the correct import of albuminuria could be judged of.

DR. KAVANAGH remarked that teachers at medical schools might perhaps examine the urine of all their students, and see what became of those who had albuminuria in the course of twenty or thirty years; medical men could be very easily traced in after-life, and thus a prognosis might be arrived at. A remarkable case of recovery from albuminuria existed in the person of a distinguished lawyer in Scotland, aged eighty, who, when a youth, had been seen by Dr. Bright and given to understand that he had a fatal disease, and was not likely to live many months. And yet he got quite well, had a laborious career, and rose to great eminence in his profession.

DR. BARR, of Liverpool, said he had long thought that in cases of albuminuria the amount of albumen passed was far too much attended to. He was accustomed to pay greater attention to the quantity of urea passed; and instead of paying attention to the kidneys in such cases, we should direct our attention to the heart and the condition of arterial tension existing. In granular kidney very little albumen was passed; but in such cases it would be found that the patient was passing as much as 400 grains of urea daily. He had always contended that in albuminuria the heart was most often in fault.

DR. HAY, of London, said that, with regard to Weston's case of transient albuminuria, the tracings showed that while he was passing albumen he was exhibiting symptoms of high arterial tension.

DR. HERRINGHAM pointed out the frequent relationship of hæmato-globinuria with albuminuria, and cited the case of an elderly gentleman who had exhibited hæmato-globinuria when coming back from a mountain ascent.

DR. GEORGE HARLEY, of London, said that the result

of the two and a half hours' discussion which had taken place was most valuable, and the British Medical Association was useful as a place for mutual instruction, and not for merely mutual admiration. He made it a rule, in the examination of patients, to pay greatest attention to the question of the specific gravity of the urine. It was not the quantity of albumen in the urine that killed; it was the retention in the blood of excrementitious substances which proved fatal in Bright's disease. The moment we had diseased kidneys we may get uræmia, uric acid, and other poisons, all of which tended toward a fatal result. Albuminuria with a urine of 1.015 was curable. Albuminuria of pregnancy and caused by great exertions, was a good prognosis. In such cases there was simply congestion of the kidney. He considered that the terms functional and physiological albuminuria were misleading, just as neuralgia was misleading, and of no therapeutic importance. The kidney had no function in eliminating albumen. It was merely a filter. The specific gravity of the urine was the important matter. The presence of albumen, whether temporary or permanent, was not, *per se*, dangerous.

THE PRESIDENT read some conclusions which Dr. Johnson, of London, had forwarded to him. These were, that the presence of albumen in the urine is always pathological; the practice of testing the urine in all cases had led to the discovery of many cases of albuminuria that would otherwise have remained undiscovered. To talk of albuminuria as physiological was dangerous; and almost all such cases might be traced back to a pre-existing causation in scarlet fever, cold, etc. On the one hand, intermittent albuminuria was curable. In doubtful cases the urine should be tested several times in the day, in order to arrive at a conclusion as to the presence or absence of albumen.

DR. EDDISON, of Leeds, was much gratified in hearing the remark of Dr. George Harley, that it was not the passing of albumen that was dangerous. It was to be regretted that the discussion on the prognosis of albuminuria had been mixed up with business transactions. A clever chemist might find out some albumen in the urine, when a physician would not find it, or care to find it. Time was requisite to make up the mind in doubtful cases of albuminuria, and the patient should be asked to return on some future occasion. He would be glad to know more about the production of albuminuria in cases of anxiety, as for instance, in positions like those he himself was occupying at that moment.

DR. PAVY, of London, in reply, said that he fully recognized that Weston's albuminuria was a pathological symptom. In great exertion there was doubtless incipient disease of the kidneys. These cases were not comparable with cases of cyclic albuminuria. The organic acids precipitated one form of albumen. The term physiological albuminuria was not tenable. It would be as sensible to talk of physiological dyspepsia; but the word functional might be allowed. Something in the body was functionally out of order. This need not be in the kidneys alone; it might be in the heart. It was not the loss of albumen that was dangerous in albuminuria, but the retention of the uric acid and excrementitious products.

DR. HAIG, of London, read a paper on

ALBUMINURIA.

He said that Professor Semmola had shown that the subcutaneous injection of albumen in animals produced not only serum albumen, but other albumens in the urine. Albuminuria might exist without any disease of the kidneys; and nephritis might be produced by the mechanical passage of albumen through the kidneys. Deficiency of activity of the skin was a frequent cause of albuminuria; and many skin diseases when cured might cause albuminuria. The functions of the skin were greatly interfered with in scarlatina, and hence the frequency of albuminuria in that fever. So too in cold bathing. It was probably, in such cases, the condition of the skin which caused albuminuria, and not that of the heart. Semmola's views were definite. Cold, damp valleys tended to cause Bright's disease, and dry climates often effected a cure of albuminuria. Deficient skin function was of utmost importance in the pathology of the disease. In some patients, when they were lying in bed, almost any kind of treatment would suffice to ameliorate cases of albuminuria; when these patients were up and taking exercise, they were often enabled to do their work with comfort under a milk diet, when any other diet would cause great discomfort and increase the excretion of albumen. The failure of the heart's action did not account for those cases where there was more albumen after meals. In these circumstances there was more albumen in the blood, and this caused the escape of it by the kidneys. It had been found that hæmoglobinuria had been produced by freezing the fingers. Dyspepsia was often produced by what had been styled an "uric acid storm." Such were Semmola's views, which he, Dr. Haig, was anxious to make known as widely as possible, as they seemed to him to contain much truth.

DR. SAUNDBY, of Birmingham, bore testimony to the great interest of Dr. Haig's former papers on uric acid, and said that there were many points in this communication with which he was in accordance.

DR. DRYSDALE, of London, said that he had on several occasions met the learned professor Semmola at the meetings of International Medical Associations, and was convinced that the views put forward by that author on the causation of albuminuria contained many most important truths. The hints given by Dr. Haig with regard to treatment, which were derived from Semmola's views as to the causation and pathology of albuminuria, such as the importance of sending patients with Bright's disease to warm and dry climates, and feeding them on an easily digestible or milk diet, were most valuable and were beginning to be appreciated. The main point, indeed, in the treatment of Bright's disease was warmth, comfort, and suitable diet. Purgatives and diuretics generally had proved very injurious in his experience of acute and chronic Bright's disease.

DR. P. MAGUIRE read a paper on

PRESYSTOLIC MURMUR WITHOUT MITRAL DISEASE.

The author brought forward two specimens to prove that presystolic murmur may by caused by other circumstances besides diseases of the mitral valve. In Case I. the patient exhibited cardiac impulse in the sixth interspace, and two murmurs were heard, a presystolic and a diastolic murmur, with a few râles at basis of the lungs. There was no pain. On October 14, 1888, the patient had an appearance of cyanosis, and on listening the murmurs were heard as usual by himself and Dr. Cheadle. The condition of the lungs was impaired. The patient left hospital, but returned with an attack of anginal character from which he died. The heart was found to be greatly enlarged. The aortic valves were diseased, but there was no narrowing of the mitral orifice. Great œdema of the lungs existed. In the second case, a patient entered St. Mary's Hospital in 1877, with diffused pulsation of the heart and other evident symptoms of cardiac dilatation. There was a diastolic murmur and also a presystolic murmur present. The patient died and the heart was found to be very greatly enlarged, weighing twenty-five and a half ounces. The left orifices were greatly dilated and the tricuspid valve diseased. An aneurism of the coronary artery bulged into the cavity of the auricle and caused the narrowing of the orifice, which had given rise to the presystolic murmur.

Dr. Eddison, of Leeds, Dr. Acland, of London, Dr. Saundby, of Birmingham, Dr. Drysdale, of London, and Dr. Maguire, discussed this paper, and doubt appeared to exist in the mind of some of the speakers, whether the presystolic murmur in these cases was not connected with the insufficiency existing in the aortic valves in both cases.

Dr. Bourne Harley, of London, read an abstract of a paper on

THE TREATMENT OF ABSCESS OF THE LIVER.

The author observed that men were much more liable to have abscess of the liver than women. When there was an abscess in the liver it was apt to cause pyæmia, if not treated by evacuation of the abscess, and hence as soon as an abscess was known to exist it should be surgically treated. A long trocar should be passed into the liver from the right side, up to its hilt, until the end of it entered the cavity of the abscess, which could then be emptied through the cannula. As much as would come away should be evacuated, and the cavity of the abscess thoroughly emptied of pus. The trocar should always be passed at the right side, and not from before backward. Dr. Harley narrated cases in which a complete cure of hectic and other alarming symptoms caused by abscess of the liver had been effected by such surgical treatment. The antiseptic used by himself in dressing the wounds of the skin was a solution of boracic acid, ten grains to the ounce of distilled water.

Dr. Eddison, of Leeds, asked whether there was not some risk of escape of blood into the peritoneum in such cases, where a vessel might be pierced by the trocar.

Dr. George Harley said that it was the rarest event, in the treatment of abscess of the liver by evacuation with the trocar and cannula, to find any blood escaping from the wound. Greatest care should be taken to pass the trocar in from the right side, and not from the front of the abdomen, as the latter method might prove fatal. When such abscesses remained untreated the occurrence of blood-poisoning was by no means uncommon.

---

SECTION IN OBSTETRICS AND GYNECOLOGY.

Thursday, August 15th—Second Day.

Dr. Herman began the proceedings of this day by reading a paper on corporeal endometritis, in which he said that some persons almost refused to admit the existence of the affection. In many cases, he said, we had nothing but inferences to guide us, but when these inferences pointed in one particular direction, we were bound to act on them. If the products of inflammation come to us from the body of the uterus, we may infer the existence of corporeal endometritis; but the pus which exudes through the cervix may come from the tubes, and not from the body of the uterus.

He recognized two forms of corporeal endometritis, viz., the hypoplastic and the polypoid. In both the uterus is enlarged and expanded. The diseased surface should be scraped with a curette, or caustics might be employed. In the polypoid form, the blunt curette is the one that should be used. The polypoid growths are most usually found in married women. The hypoplastic is met with at all ages. The relation of corporeal endometritis to cancer is very uncertain, and of the affection as arising from gonorrhœa very little is known. Endometritis is undoubtedly the result of specific fevers, as post-mortem research has demonstrated its existence.

Acute endometritis is sometimes accompanied by severe pain and fever, but when these are present in a marked degree a more grave affection than endometritis may be suspected.

In the treatment the chief indications were to look for and remove the cause, when the disease would disappear, whereas, if left to itself, it would spread to the tubes. Dr. Herman drew attention to the different temperaments of patients, and said we must discriminate the symptoms of the disease from what he called the symptoms of the patients. He does not look upon this affection as due to obstruction of the cervical canal, though local treatment often alters the conditions which have induced the disease. Active intra-uterine treatment, he thinks, is not advisable in slight cases.

Dr. J. W. Byers opened the discussion on Dr. Herman's paper by alluding to the treatment of endometritis, which was chiefly by the use of caustics, or the curette. The object of both is the same, viz., to remove diseased growth, but caustics do not do this so quickly as the curette. Of the two forms of curette (sharp and blunt) Dr. Byers preferred the sharp instrument, as it removes what the blunt will often merely pass over. The curette must be used with antiseptic precautions. He had generally found corporeal endometritis most troublesome in nulliparous women, and in their case he had often been inclined to attribute the disease to gonorrhœal infection. Hemorrhage was not always a symptom of endometritis, and the diagnosis between this disease and cancer was one of great difficulty. Dr. Byers thought that Dr. Herman "fought shy" of intra-uterine medication, which is most useful and important.

Dr. Routh thought that by means of Simpson's instrument for applying caustic to the interior of the uterus, we can obtain some of the secretion at its fundus, and determine the nature of this secretion, which will materially assist us in forming a diagnosis in cases of endometritis. In the treatment of this affection, Dr. Routh insisted on the necessity of fully dilating the cervical canal in the first place, and then in the use of powerful intra-uterine injections, being careful to see that they had free exit and came away. From our knowledge of uterine innervation and the sources from which the various uterine zones derive their nerve-supply, he thought that we could diagnose to a great extent the exact locality of intra-uterine inflammation. As regards the spread of gonorrhœal inflammation to the tubes, he thought that any case of intense vaginitis will affect the tubes independently of gonorrhœa. Some say that when urethritis exists it is due to gonorrhœa. Dr. Routh was not sure of this point, but he was satisfied that in every case of urethritis there is affection of the tubes. In the case of children who have suffered from a vaginal discharge, corporeal endometritis does not follow as a necessary consequence in after-life.

Dr. Graily Hewitt said that to understand fundal endometritis we must go back to first principles and take into consideration the fact that the alterations which occur are dominated by the circulation. In other words, that congestion precedes endometritis. The hypertrophy due to menstruation is also of consequence in reference to this consideration. Besides this, one cause of congestion of the uterus is often found to be displacement of the organ. Then the weakening of the circulation and local circumstances augment this. As regards hypersecretion, it must be remembered that the tubes themselves secrete, and the question arises whence does the discharge come, from the uterus or from the tubes?

As regards the polypoidal variety, he mentioned the case of an unmarried lady supposed to be suffering from malignant disease of the interior of the uterus. The os was large and a soft mass could be felt by the finger, and it was determined to remove the mucous membrane; but after the preliminary rest in bed before the operation, it was found that when the patient was placed on the table there was nothing to remove, as the hypertrophy of the mucous lining was gone, although the uterus was enlarged and acutely anteflexed. The speaker also insisted on the necessity of enlarging the cervical canal before adopting intra-uterine medication.

Mr. Pridgin Teale said that, owing chiefly to the labors of the Dublin gynecologists, we are now able to deal with the interior of the uterus in a way we could not venture on before. In dealing with the interior of the organ we must begin by dilating the cervix, and as in dilatation of urethral stricture, so in dealing with the os uteri, moderately rapid dilatation was advisable. We need not now use tents for this purpose, their action is too slow. In dealing with unmarried women, they should be examined under ether, in the lithotomy position, the os should be dilated as directed above, when the curette may be employed or medicaments applied to the interior of the

uterus. Success depends in a great measure on drawing down and studying the os, and for this purpose Mr. Teale exhibited a pair of forceps which he had found most useful.

Dr. R. Bell, of Glasgow, thought corporeal endometritis was a common disease, and that there was but little difficulty in its diagnosis. One pathognomonic symptom was the great effect it produces on the nervous system. When pus is discharged from the tubes, he thought it had previously travelled to them by continuity of tissue from the uterus. Corporeal endometritis was not, he thought, spontaneously curable and, if not interfered with, the interior of the uterus would go on generating pus *ad infinitum*. Dr. Bell alluded to some points of apparent similarity in cases of corporeal endometritis and of cancer.

Dr. More Madden in his remarks dwelt chiefly on the treatment of this affection, and said that the present means of rapid dilatation had done more than anything else in helping us to treat these cases. Endometritis is not limited, he thought, to any particular zone of the uterus. He exhibited ergot largely, scraped the interior of the uterus with a sharp curette, and washed it out with warm water.

Dr. Braithwaite thought that dilatation need not be carried so far in endometritis as in dysmenorrhœa. Curetting was useful in chronic cases, but it must be remembered that it caused the uterus to bleed, which would interfere with the application of medicaments.

Dr. Handfield Jones deprecated excessive dilatation of the cervical canal, and thought the dull curette a preferable instrument to the sharp one for dealing with the interior of the uterus.

Dr. A. Duke preferred the sharp curette, and laid stress on keeping the cervical canal patulous.

Dr. Walker thought uterine flexions played an important part in these cases. The nervous condition present was also important, and must not be overlooked. It showed the necessity for general treatment. Discharges from the vagina in children generally occurred among the poor, and were due to a want of cleanliness, and also, perhaps, to the child sitting on a cold stone.

Dr. Murdock Cameron thought that over-rapid dilatation of the cervical canal was not unattended with danger, owing to the risk of its causing cellulitis. He preferred the use of the dull curette, and advocated the employment, for the same purpose as a curette, of a metal brush similar to that used for cleaning the interior of a rifle-barrel. Carbolic acid and spirits of wine in equal parts, he considered a useful intra-uterine medicament in these cases.

Dr. Horrocks thought the diagnosis of corporeal endometritis was difficult, owing to the insufficiency of our knowledge of the process of inflammation. He alluded to the frequent occurrence of endometritis in women of intemperate habits.

Dr. Handfield Jones then read a paper on

CARDIAC INSUFFICIENCY IN ITS RELATION TO ABORTION.

He said no great advance had been made of late in deciding the question of the influence of the condition of the heart on pregnancy. Stenosis of the mitral valve is said to give rise to abortion, but he thought valvular disease did not interfere materially with pregnancy. There is a normal hypertrophy of the heart in pregnancy, chiefly affecting the left ventricle. If this ventricle is vigorous, the blood-stream reaches and nourishes the enlarging uterus. He said heart distress commenced generally about the third month, and was very often due to the absence of the compensating hypertrophy he had just spoken of. A feeble left ventricle gave rise to stagnation of blood in the capillaries, which bulge and break, causing extravasations of blood, which separate the ovum from the uterus.

Dr. Murdock Cameron exhibited drawings and read some most interesting notes on two cases in which he recently performed

CÆSAREAN SECTION

successfully in Glasgow.

Dr. Arthur Roberts read a paper on

CONCEALED ANTE-PARTUM HEMORRHAGE.

He mentioned some cases in his practice where pain, faintness, and sickness were the chief evidences of the occurrence of this complication. The pain and sickness, he suggested, might be due to the stretching or tearing of the peritoneum. The prognosis in these cases is very serious, and the treatment recommended is rupturing the membranes, and then waiting for nature to complete delivery.

---

Friday, August 16th—Third Day.

In the absence of Dr. W. S. Playfair, a written paper by him was read by Mr. Wheelhouse, entitled

AN ESTIMATE OF THE VALUE OF ELECTRICITY IN GYNECOLOGY.

Dr. Playfair thinks hysterectomy is not a legitimate operation until electricity has been tried and has failed. The spontaneous absorption of fibroid tumors was also alluded to as having saved patients from hysterectomy. He also drew attention to the hæmostatic effects of electrolysis, which is a strictly conservative operation. Membranous dysmenorrhœa is also much benefited by electricity, and the negative current is most beneficial in cases of inflammatory exudation which are of long standing and perfectly chronic.

Dr. Ephraim Cutter, of New York, gave some details of eighteen years' work in the United States, in the treatment of uterine fibroids by galvanism, and described the method of operating; and he also gave some statistics of the treatment of uterine fibroids by food for the same length of time.

Mr. Lawson Tait criticised very freely Dr. Playfair's paper. He said that in two hundred and sixty-two cases in which he had removed the uterine appendages, the mortality was only 1.23 per cent. He thought Dr. Playfair's statements too vague, and that there was no value to be attached to any such statements unless the actual number of cases which had been dealt with by electrolysis and the results were given. This line of treatment should first be tried in more superficial tumors, and its results noted in such cases. He dealt in what he called the intrinsic and extrinsic causes of mortality; the former, which were faults that it was in the power of the operator to avoid, must be eliminated, and only the extrinsic taken into consideration, and he thought that it will be proved that the mortality in cases of hysterectomy would not contrast unfavorably with that in cases treated by electrolysis. As regards one objection to the performance of hysterectomy, viz., that it unsexed the patient, he said that it must be borne in mind that the cases for which the operation was performed also interfered with the prospects of maternity.

Dr. Parsons said that as much accuracy should be observed in laying down treatment by electricity as is used in defining treatment by the exhibition of quinine or opium or mercury. He said we wanted assurance that the so-called cases by electrolysis were complete.

Dr. Imlach said that this was now the third occasion on which treatment of fibroids by electricity had been brought before the Association, without any reliable information as to its beneficial results having been laid before the meeting.

Dr. Horrocks said that the electrical treatment of fibroids was still *sub judice*, and as regards Mr. Lawson Tait's two hundred and sixty-two cases of hysterectomy with a mortality of only 1.23 per cent., he would wish to ask how many of the two hundred and sixty-two were now alive. Fibroids, he said, are not necessarily fatal, and if the two

hundred and sixty-two had not been operated on they might probably be all alive now. The constant current he looked on in the light of a caustic, its energy dependent on the number of cells used.

DR. BYERS said that if a Hindu surgeon had been listening to the discussion to-day, he would be puzzled how to act. It must be remembered that different cases required different modes of treatment.

DR. MURDOCK CAMERON complained that sufficient details had not been given, more particularly with regard to the depth of the punctures in the treatment of fibroids by galvanism.

DR. BELL thought that Mr. Tait's comments on Dr. Playfair's cases, which he (Mr. Tait) had not seen, were somewhat unfair, and Dr. Bell welcomes the discussion of any procedure, such as electrolysis, likely to do away with more severe surgical treatment.

DR. GRAILY HEWITT said that we needed more facts before coming to a conclusion. His experience of the electrical treatment of fibroids had not been fortunate.

DR. BRAITHWAITE used electricity in fibroid cases. He thinks it produces absorption of the tumors, but it is not applicable to every case, and there are difficulties in the way of its use in hospital practice, particularly with out-patients.

Drs. Routh and Madden continued the discussion on Dr. Playfair's paper and Mr. Lawson Tait's criticisms of it, and the President wound it up by saying, in reply to Mr. Tait's suggestion of our first dealing with superficial tumors, that he had tried electricity in the case of a very large bronchocele. After five applications it began to diminish considerably, and all difficulty of breathing, which had been very urgent, disappeared. More facts and statistics, he thinks, are needed to enable us to decide on the relative merits of the different modes of treatment of uterine fibroids.

---

## SECTION IN SURGERY.

### THURSDAY, AUGUST 15TH—SECOND DAY.

MR. HENRY MORRIS read a paper on

### SURGERY OF THE KIDNEYS.

The various ways in which calculi are embedded in the kidney, he said, required special precautions while operating. Tubercle of the kidney might give rise to the same tactile impressions as small calculi. Tubercular disease of the prostate gland was a source of fallacy in diagnosing renal calculi. Nephrectomy was of very doubtful value in advanced tubercular disease of the kidney. Lumbar nephrectomy was the proper treatment for advanced hydronephrosis and for large collections of fluid behind the peritoneum, the result of lacerated kidney. In these cases, nephrectomy, without previous incision and drainage, should be more frequently resorted to than has been the practice hitherto. Nephrorrhaphy for movable kidney was often of great service. Finally, Mr. Morris said, the changes which the perinephritic tissues undergo under long-continued irritation sometimes rendered the search for the kidney very tedious and difficult.

MR. BENNETT MAY said he had operated for

### STONE IN THE KIDNEY

on fifteen patients—twelve males and three females. He thought we might group cases according to the way in which the stone was placed in the kidney. In at least half the cases it was embedded in the cortex, away from the pelvis, and was mostly of slow growth. Such calculi were usually limestones, and occurred in young men. Nearly all the patients had been bedridden for years before being operated on. A diagnostic sign was pain on deep pressure under the last rib, accompanied by crystals of oxalate of lime and uric acid in the urine. Traces of blood were passed in micturition, more after exercise. The urine contained no pus. These cases gave the best results, because the patient was cured by operation. In several there was a narrow escape of the patient leaving the table with the stone undetected. There was no hope of finding the stone by palpation. He had used an acupuncture needle, passed in from the outer border of the kidney, and particularly passing it from below upward. A search should always be made for a second stone, which existed in three of his cases. The other group of cases comprised those in which the stone was in the pelvis of the kidney. Pus in the urine was an early symptom, but pain might be absent. The stone might be very small indeed, and give rise to symptoms of obstruction of the ureter. He disapproved of nephrectomy in tuberculosis of the kidney.

DR. NEWMAN, of Glasgow, said few cases of movable kidney required operation. He usually treated them by applying an elastic abdominal bandage, fitting accurately, so that the pressure was equal over the entire abdomen. In many cases the kidney became fixed and the adipose tissue around it increased. In calculus we should operate early, before suppuration had occurred; the operation was then safe. The aim of the surgeon should be to bring out the points necessary to make a successful diagnosis. Catheterism of the ureter was useful, and facility might be gained by practising on the dead body, in which it was more difficult than in the living patient. It was also useful as an aid to diagnosis to estimate the quantity of blood pigment in the urine. In a case of renal calculus where a patient refused operation, we should treat the case by perfect rest, in the hope that the calculus, if in the pelvis, might become encysted.

MR. LAWSON TAIT, of Birmingham, said he had operated on seventy-five cases of kidney disease, with six deaths. Four of his operations were exploratory incisions; there were four nephrotomies (with one death), twenty-one nephrectomies (with three deaths), and four nephrorrhaphies. In discussing the question of mortality we must not mix up primary and secondary operations. The mortality of ovariotomy had virtually disappeared since early operation had become the rule; similarly, many a kidney might be saved if early nephrotomy were performed instead of a late nephrectomy.

### HE REGRETTED HIS OPERATIONS OF NEPHRORRHAPHY.

None of the patients had been benefited, and one had since died under circumstances which might fairly be attributed to the operation. He would himself have nothing further to do with the operation of nephrorrhaphy. In operating on the kidney he believed it was of no consequence whatever whether the peritoneum was opened or not. Referring to the uncertainty of diagnosis, he observed that the proportion of mistakes in diagnosis was about the same as in other abdominal cases—about ten per cent. Tubercle of the kidney might possibly give rise to the same tactile impressions as calculus, but as to this he had no experience. Nephrectomy was of very doubtful value in advanced tubercular disease. His treatment for hydronephrosis was to open and drain it, and he would remove no kidney till it had had a chance for repair. As to lumbar nephrectomy being the proper treatment for advanced hydronephrosis, his own opinion was the exact opposite. He also did not agree with Mr. Morris that the changes which the perinephric tissues underwent under long-continued irritation, sometimes rendered the search for the kidney tedious, difficult, or even ineffectual; that was not yet his experience.

MR. BRUCE CLARK said he had operated on seven cases—on one twice over. In this case the kidney had a complete mesentery. He found no stone, but sutured the kidney to the body-wall. Pain was relieved for a time, but returned. He operated again and incised the kidney. Failing to find any stone he removed the kidney, and on examining it after removal it was only after the most careful and prolonged search that he found a small calculus the size of the end of a pencil. One of his cases died. Vomiting followed the operation and suppression of urine (affecting both kidneys); at the post-mortem

suppuration was found in the peritoneum near the kidney. He did not think nephrorrhaphy so useless an operation as did Mr. Lawson Tait. He had had four cases, and believed that in cases of movable kidney pain would generally be relieved by passing sutures three-fourths of an inch through the substance of the kidney and fixing the kidney to the body-wall. In performing nephrectomy he thought it a good plan, if removing the kidney from the loin, to stitch the edge of the capsule to the skin. By so doing, the wound was shut off from communication with the ureter. It was, however, sometimes not possible to stitch the capsule to the edges of the wound.

MR. KENDAL FRANKS, of Dublin, remarked that a certain amount of benefit did sometimes follow exposure of the kidney, but it was generally only temporary.

REMOVAL OF THE KIDNEY

was a severe procedure; it was far better to incise it, which was not a formidable proceeding. It was better to search for the calculus in the kidney while the kidney was still a part of the patient's body, than when it was on the dissecting-table. With one modification (viz., making pressure on the kidney when the patient was on his face), he agreed with Dr. Newman that pain on pressure was a valuable sign of calculus. Alternating pain, varying with posture, was a sign of value. The wound in the loin should be left freely open. In one case he plugged it with gauze; vomiting followed the operation and was persistent, in spite of trying all the remedies he could think of, until the plug was removed, when it ceased. In many kidneys, small blood-clots formed which might form the nuclei of future stones, unless they were washed out by the flow of urine. He regarded excision of the kidney in early scrofulous disease of the organ as a surgical procedure which should be adopted.

MR. LAWFORD KNAGGS, of Huddersfield, observed that the passage of bloody urine after operation might suggest congestion of the opposite kidney, but some of it might come from the kidney which had been removed.

DR. IMLACH, of Liverpool, said he had removed the kidney in hydronephrosis. In pyonephrosis the kidney would not grow beyond a certain size, the pus being limited by thickened and inflamed tissue.

THE PRESIDENT then called upon Mr. Morris to reply, and asked him which method he adopted in performing nephrectomy?

MR. HENRY MORRIS then replied. In response to Mr. Jessop's query, he said he adopted different methods of nephrectomy in different cases. He was not in favor of nephrectomy for malignant disease, but in dealing with large malignant masses the anterior incision was the best. He preferred Langenbeck's incision at the outer edge of the rectus. For calculus and tubercular disease he preferred the lumbar operation. He disagreed with Mr. Bennett May about palpation being useless, and said that in some cases the stone could easily be felt; he agreed with him as to the method of puncturing—in lines radiating from the convex border of the kidney. In all his cases he had tried rest, pads, etc., before operating, but he had not tried the ring pad. He did not agree with Mr. Lawson Tait that nephrorrhaphy was a useless operation. He would freely incise before excising the kidney; he did not do so in his first case, but recommended it immediately afterward from his experience in that case. In hydronephrosis the kidney substance was almost or entirely destroyed. He therefore advised removal of the kidney in such cases and disagreed with Mr. Tait; of course he would not remove the kidney without clear evidence of the other kidney being present. When we knew a sinus would continue discharging, it was better to remove the kidney; the fluid discharged was of low specific gravity and was not urine. He referred to the case of a patient whom he tapped for hydronephrosis and let out two wash-hand basins full of fluid and blood; now (five years afterward) there was a sinus remaining through which about twelve ounces of fluid were discharged daily. The patient was in good health and was not willing to submit to another operation, but no doubt he would have been thankful if his kidney had been removed at the former operation, and his present inconvenience thereby avoided. Mr. Bruce Clarke's method of stitching the capsule to the wound was good, but in cases where there had been inflammatory troubles it was difficult to shell out the kidney without breaking through the fibrous capsule. Such a procedure, also, was not practicable in hydronephrosis, where we had little to deal with but a fibrous capsule which collapsed immediately it was punctured.

MR. FREDERICK TREVES then opened a discussion on

THE SURGICAL TREATMENT OF TYPHLITIS.

Typhlitis, he said, was a localized form of peritonitis. If it resulted in suppuration the pus might be encysted. It differed from other localized forms of peritonitis in its site and mode of causation. Numerous terms were at one time used to describe various forms of the affection. There was no reason to suppose that primary inflammation ever occurred, apart from catarrh or ulceration of the mucous membrane. The symptoms produced by catarrh of the cæcum were not those of typhlitis, but those of colitis. Ulcer of the cæcum would not produce symptoms of typhlitis until it had extended to the outer wall of the cæcum. Perforation of the cæcum was rare as a primary condition; Fitz had recorded three cases. Abscesses from cæcal trouble were primarily intra-peritoneal; the cæcum and appendix were entirely surrounded by peritoneum. The milder varieties of typhlitis were usually caused by peritonitis over the cæcum; the graver forms by disease of the appendix. He had found that twenty-five fatal cases had occurred in the London Hospital during a period of several years. In one case a patient had had fourteen attacks of typhlitis, and on exploration a diseased appendix was found, but no pus. Fæcal concretions were present in the appendix in about half the cases. Perforation was common, and was sometimes found without any foreign body being discovered. Typhlitis might occur in very varying degrees. Firstly, there was the mild common form, which usually ended in resolution. This generally depended on fæcal lodgement in the cæcum and a stercoral ulcer formed. This form was more common in males; thirty-six per cent. of the patients were under twenty, and only twenty-one per cent. over forty. The patients were usually constipated and the pain appeared suddenly. There was seldom any rigor. The tumor formed early and was large and doughy. Bladder troubles were usually absent. The second variety was severer and led to suppuration. More than half the cases were over twenty-one years of age. There was often a history of cold or injury. The pain was radiating, and associated with tenesmus and troubles in micturition. The third form was the familiar form of

RELAPSING TYPHLITIS.

The affection sometimes became more severe after each attack; it never led to suppuration. Cases of the first mild form did very well under the recognized medical treatment, viz., rest, opium, little fluid to drink, leeches, fomentations, and the evacuation of the colon by means of enemata. When suppuration occurred, or was expected, surgical measures were called for. It was seldom necessary to make an incision before the fifth day, and it was not advisable to do so unless there were urgent symptoms. In most cases an incision should be made only after the first week. The abscess should be opened after it became encysted, so as to avoid opening the general peritoneal cavity; this could hardly be done if it were incised in thirty-six hours, as advised by some. He did not approve of the exploring needle for such cases. Deep-seated pus, sufficient in amount to cause serious symptoms, could be diagnosed by other means, and careful incision was preferable. The use of the needle was not free from danger, though it was perhaps unfair to suggest that suppuration was caused by it. But bloody pus had been

found in cases where the needle had been used repeatedly, and in some cases where no pus had been found by the needle it had subsequently been found by incision.

PERHAPS THE NEEDLE WAS SAFE

in the hands of Dr. Bull, of New York, but if its use became general we should have the opportunity of ascertaining the effect of passing a needle, first through diseased and suppurating tissues, and then into the iliac artery or other organs. The site for incision was in the iliac region, outside the deep epigastric artery—just above and outside Poupart's ligament. Some had recommended scraping the abscess cavity with a spoon, also that foreign bodies should be searched for. It had also been advised that the diseased portion of intestine should be excised and the ends united by a plastic operation. He considered that

SCRAPING WAS CRIMINAL.

Incision should be free and foreign bodies should be searched for, but the less done to the appendix at the time of operation the better. The state of the tissues was not such as to favor a plastic operation, and he objected to excising portions of the cæcum; the fistula in the cæcum would do well in most cases if left alone, with rest and a careful selection of food. The proper

TREATMENT FOR RELAPSING TYPHLITIS

was to remove the appendix. He had first urged this in 1887, and thought no surgical procedure gave such good results. We should operate between the attacks, when the patient was well, and remove the diseased appendix. The patient would recover from a simple abdominal operation and have no recurrence of the typhlitis. The condition of the appendix varied. One patient had had fourteen attacks, and had been in bed twelve months when the operation was done. The peritoneal cavity must be opened. The appendix must be lightly clamped and cut off. A double row of sutures should be placed in the stump, which should be attached to any neighboring piece of peritoneum. During the operation the general peritoneal cavity should be separated off from the site of operation by sponges interposed. In some cases the appendix could not be removed, in others there was danger that the ureter might be removed under the impression that it was the appendix.

MR. BENNETT MAY commented unfavorably on the advice given by certain American surgeons, to operate within a week unless recovery had taken place. We should endeavor, he said, to distinguish between perforative and non-perforative cases. It was not easy to diagnose perforative cases. The simpler the operation the better; a drainage-tube should be employed. He had found considerable trouble from hemorrhage.

DR. EASTES related a case in which prompt relief was afforded by opening posteriorly an abscess in the iliac region; a glass drainage-tube was inserted.

Mr. Lawford Knaggs, Dr. Beale, and the President having spoken, Mr. Treves then replied. Commenting on a case narrated by Dr. Beale, he said he thought that case should have been operated on. There was no other known diseased organ in connection with typhlitis but the appendix. The latter was an obsolete organ, and the risk of removing it was not to be compared with that of relapsing typhlitis.

MR. MAYO ROBSON then read a paper in which he gave an account of one hundred and eighty-eight consecutive cases of

ABDOMINAL SECTION.

The peritoneum had been opened, he said, in every operation included in his list, from which he had excluded all cases in which it had not been opened. He agreed with Mr. Tait as to the difficulty of diagnosis, and the proportion of cases (ten per cent.) in which mistakes were made. He thought the motto of the surgeon should be, "When in doubt, operate." His list included 61 cases of ovariotomy, with only 2 deaths, and 56 consecutive recoveries. These were all operated on in a general hospital, with the aid of antiseptics. The cases were not selected. He would always operate on any case in which there was a chance of doing any good. The largest amount of fluid removed from any single cyst was ten and a half gallons. The heart was pushed up and was beating in the second space. The patient made a good recovery. There were 14 cases of abdominal section for fibroids, with 3 deaths, and 2 cases of suprapubic hysterectomy (1 death). Seven operations were exploratory, of which three terminated fatally. There were six operations (all successful) for pelvic abscess. The abdomen was opened five—or, including one of the exploratory operations in which this condition was found, six—times for tubercular peritonitis; all the patients recovered. Abdominal nephrectomy was performed in one case; a large cyst was found, and the patient died from acute mania in the third week. There were 2 cases (both successful) of hepatotomy for hydatids; 11 of cholecystotomy, of which number all recovered but 1, in which there was cancer of the pancreas. There was one (successful) case of cholecystenterostomy (patient shown on previous day). He had operated fourteen times for intestinal obstruction, with four deaths. He believed most of the deaths following operation in such cases were due to shock, and he would never again spend a long time in searching for the cause of obstruction, but, if it were not soon evident, bring up a distended coil of intestine, attach it to the edges of the wound, and open it twelve or fourteen hours later. There were 59 cases of hernia, of these 30 were cases in which herniotomy was performed for strangulated hernia, and there were 24 recoveries, with 6 deaths; 29 were cases in which the operation for radical cure of hernia was performed, with only 1 death. There were two cases of gastrostomy, with one death, and three cases of abdominal section for perforating peritonitis, all of which ended fatally.

---

FRIDAY, AUGUST 16TH—THIRD DAY.

MR. A. F. MCGILL, of Leeds, opened a discussion on

THE TREATMENT OF RETENTION OF URINE FROM PROSTATIC ENLARGEMENT.

Mr. McGill remarked that in many of these cases self-catheterization was the only treatment needed; when this failed, or was unavailable, further treatment was necessary. Suprapubic prostatectomy was preferable to a urethral or perineal operation. The urethral operation was unsatisfactory; it was founded on faulty anatomy, for in only 4 out of 24 cases he had tabulated was there anything resembling a bar at the neck of the bladder. The suprapubic operation was also more generally applicable; in only 3 of the 24 cases in his table could the perineal operation have been done. He considered the suprapubic operation compared favorably with others as regarded safety, but it was not possible to show this from statistics; many of his cases were in old men. In performing the operation he thought the quantity of water injected into the rectal bag should be smaller than that generally recommended; from six to ten ounces was usually sufficient. A catheter should be passed, and left in until the finger entered the bladder. The bladder should be irrigated with an antiseptic solution until the latter came away clear. The prostate should, as far as possible, be removed by enucleation with the fingers (a manœuvre first practised by his colleague, Mr. Atkinson), and not by cutting, though the middle lobe might be cut through at its base after the mucous membrane had been snipped through. Bleeding might be checked by irrigating the bladder with water so hot as to be unpleasantly warm to the hand. Mr. McGill presented a table showing the previous history, condition at time of operation, date and nature of operation, subsequent history, and final result of 24 cases, operatively treated by himself, or one of his colleagues, at the Leeds Infirmary, from March 24, 1887, to July 11, 1889. In 7 of these there were symp-

toms of stone, and lithotomy was combined with prostatectomy; calculi were found in all these cases—in one case fifty small ones. Only one of these seven cases died, and he was a man, aged seventy-three, who was admitted for retention, and was in a very bad general condition; at the post-mortem many spots of commencing suppurative nephritis were found in the right kidney. Of the six remaining cases, one was not traced, in one there was no improvement since the operation, one continued well for three months and then another calculus formed in the bladder, and the other three (aged fifty-three, sixty-three, and seventy, respectively) were doing well. In the 17 cases in which suprapubic prostatectomy was performed without lithotomy, there were 3 deaths, viz., two within twenty-four hours (one of these from hemorrhage), and one four weeks after the operation. In the latter case the kidneys were found to be granular, and there was a large abscess in the retropubic space. Two other patients also died, but not from the operation, which was successful. One of these died from pneumonia six weeks after the operation; the other became insane and died ten months after operation. In one case, owing to the exceptional hardness of the prostate, only a piece the size of a small pea could be removed, with difficulty. The wound closed a month after operation, but the symptoms were not relieved, so the wound was reopened and a permanent fistula made. The patient (aged seventy-two) was at present confined to bed and wearing a suprapubic urinal of Mr. Buckstone Brown's pattern; but the urine was so very thick that it would hardly pass the pipe. One patient was much relieved, but there remained a very small sinus leading down to the bladder. One patient could not be traced. In the remaining ten the results were good. Seven of these cases were completely successful; in the other three there were occasional bladder troubles. Mr. McGill remarked that fifty-four had been given as the lowest age at which grave enlargement of the prostate was met with, but one of his patients was only fifty-three. This was the first case in his table, and one in which both prostatectomy and lithotomy had been performed; the prostate was the size of a large walnut, and surrounded the urethra like a collar. The credit of inaugurating this operation of prostatectomy was due to Dr. Belfield, of Chicago, who first performed it in 1886.

Mr. Atkinson, of Leeds, supported Mr. McGill in the views the latter had put forward. He had himself had five cases (included in McGill's table), with one death. In the four cases which survived, the patients could not only retain, but could also expel, their urine; they were not only able to tolerate their condition, but were comfortable.

Mr. Reginald Harrison, of Liverpool, said that in many cases the irritation caused by an enlarged prostate was far greater than that caused by a calculus or tumor in the bladder. Cases in which there was enlarged prostate might be divided into two classes: (1) those in which obstruction was the leading symptom; (2) those in which there was, in addition, intense vesical obstruction. Mr. McGill's operation gave the operator the advantage of seeing what he was doing. The early treatment of prostatic obstruction was important. This was a subject much neglected. Some years ago he had advised the use of prostatic dilators similar to those employed for urethral stricture. He referred to an instrument made at his suggestion by Messrs. Tiedemann, of New York, for exercising pressure upon any part of the prostatic ring. He had also devised a prostatome, which had been made by Messrs. Kroline & Sesemann.

Mr. Bruce Clarke remarked the obstruction to the flow of urine depended on two causes, viz., (1) on the prostate extending down the urethra, and (2) on the prostate obstructing the exit of urine from the bladder. He agreed with Mr. McGill, that it was impossible to find out the cause of obstruction by examination per rectum. He had performed suprapubic prostatectomy in two cases. In one case, which was complicated by the presence of a stone in the bladder, the peritoneum was found to be attached to the bladder, and he performed the operation in two stages.

Dr. Ward Cousins, of Southsea, said he had performed two suprapubic operations for the relief of urinary obstruction. Both patients were old men, seventy-eight years of age, and in both the obstruction was found to be due to epithelioma, masses of which he enucleated from the bladder with his fingers. The patients lived two or three weeks in perfect comfort. His chief experience was in median cystotomy; one patient, aged eighty, on whom he had performed this operation, was still passing a short tube by the perineum. He believed acute symptoms resulted from neglected chronic retention. The catheter should be resorted to in time. The necessity of commencing catheter-life could be determined by injecting water into the bladder and seeing how much would be retained. There was a dodge in passing a prostatic catheter. The surgeon should take one with a long beak, pass it right down (the patient being at the edge of the bed), withdraw it an inch, then turn it toward the right or left, depress the handle, and the point would usually jerk into the bladder. When there was cystitis he would inject a solution of boric acid—not more than two ounces; if pain were present he would add some cocaine.

Mr. Jordan Lloyd, of Birmingham, said he could see, from observing the specimens exhibited, that he had not cut freely enough in his own operations. Patients could not be got to use the catheter diligently and intelligently. It was a fallacy to expect always to find an enlarged bladder in cases of retention; when the bladder was contracted it would not enlarge, but no more urine would be secreted. He had not himself been able to shell out prostatic tissue with his fingers.

Mr. Bennett May had not found the removal of prostatic tissue easy, and had been much troubled by hemorrhage.

Professor Trendelenberg spoke of the value of placing the patient in an inverted lithotomy position—the head and shoulders being lower than the pelvis. The peritoneum was thus prevented from interfering with the bladder, and the water-bag in the rectum was not necessary. This position was also valuable in laparotomy. Some weeks ago he had operated for vesico-vaginal fistula by opening the bladder above the pubes; the fistula was high up and near the ureter, which might have been tied if he had operated in the ordinary way. In opening the bladder he made a transverse incision, which gave plenty of room. Some photographs were handed round showing how the interior of the bladder and the orifices of the ureters were exposed to view.

Dr. Hern, of Darlington, spoke of draining the bladder by the urethra, and said we should attempt to get primary union of the suprapubic wound in the bladder.

Dr. Macewen, of Glasgow, said that in one case he had had to make a large wound in the bladder, and it had healed in time extremely well.

Mr. McGill then replied. He thought Mr. Harrison's plan of dilating the prostate one of doubtful value, and he did not approve of the prostatome. With regard to drainage by the urethra, he did not like to make a wound at the neck of the bladder without providing for drainage.

Professor Fraser, of Dublin, then read a paper entitled

A METHOD BY WHICH THE HUMAN BODY, WITH ALL ITS DETAILS OF STRUCTURE, HAS BEEN MADE PRACTICALLY TRANSPARENT FOR OPERATIVE SURGICAL PURPOSES,

in which he described how, by means of a series of plates he had prepared (from sections) and a system of measurements, the exact position of any deep-seated organ could be ascertained.

Mr. William Adams then read a paper

ON THE SUCCESSFUL TREATMENT OF CASES OF CONGENITAL DISPLACEMENT OF THE HIP-JOINT BY COMPLETE RECUMBENCY WITH EXTENSION FOR TWO YEARS.

Mr. Adams maintained that if the head of the bone could be kept in the same situation for two years, the capsule

and the surrounding structures would adapt themselves to their new position.

Dr. Otto Keller read a paper on

TREPHINING IN A CASE OF ACTINOMYCOSIS OF BRAIN.

He had had, he said, two cases of actinomycosis. In one, there were first thoracic and then cerebral symptoms. The patient (a man aged forty) was operated on, and the masses of actinomycosis removed, trephining being employed to remove the cerebral mass. The patient made a good recovery from the operation, but six weeks afterward some weakness of the left arm remained. At the end of a year Graefe's symptom was present, and vomiting returned. Trephining was again performed, but the patient died. Dr. Keller said he had not been able to find any similar case on record.

## Correspondence.

### DETERMINATION OF SEX.

To the Editor of The Medical Record.

Sir: In reading the widely differing theories of medical men, and men not medical, as to the factors which determine sex in the fœtus, one cannot fail to be struck with the fact that the question is in a deplorable muddle. We may be inclined to laugh at the Hippocratic idea of tying up the right or left testicle, before intercourse, according to the sex desired; but there is evidently very little more sense in many of the modern theories.

While one claims that the result of procreation before midnight will be a boy, and after midnight a girl—another that it depends on the relative ages or vigor of the parents—and another that it depends on the menstrual period occurring before or after intercourse—it becomes pretty clear that the exact determining causes are not clear to the medical profession.

Still another theory has been advanced (I believe first by a layman), to the effect that, if at the time of copulation the preponderance of amatory desire was by the father the child would be a female, and *vice versa*.

This last theory is not even mentioned by medical writers, who yet give great prominence to those above. Without being understood as holding to this theory untested, I wish to ask, Why the silence of the medical profession in regard to it? Is it any more absurd, or less likely to be correct than any of the others? I think every candid seeker after truth is compelled to admit that it is as likely correct as any yet advanced.

It is well known that an intimate relationship—but too imperfectly understood—exists between the physical or psychical condition of the parents and conditions or characteristics in the offspring. Is it too much for us to believe that on the line of this relationship may be found the determining factors of sex?

It will readily be seen that this theory, viz., that if at the time of coition the desire for the act be mainly or entirely on the part of the husband, the intercourse, if fruitful, will result in a female child, and a male child if the desire be mainly or entirely on the part of the wife—involves in its consideration the handling of the most delicate affairs of conjugal union.

From the very nature of it, it is impossible for any one man to pronounce this theory correct, from experiments witnessed, or testimony which he may be able to gather from the laity. It is not a matter which one man can devote his life to testing, while the rest of us sit down to await his verdict.

If it is ever decided, it must be by the concurrent reports of almost the whole profession, and since our profession is happily not condemned to bachelorhood, what more trustworthy source of evidence could be had than the domestic experiences of physicians themselves? Such experiences could be reported at suitable intervals to convenient centres, and in ten years a mass of evidence would be available to fully determine the question.

A candid man would not confine himself to a prejudice, or any one theory, but would make careful note of the circumstances attending each act of intercourse (which acts, of course, must be limited in number), and the full data—not his conclusions—sent in to the central bureau.

I do not consider myself sanguine at all when I say I believe that if some such plan were carried out it would enable our profession to clear up at least one mystery, and that, too, in but a short time.

James B. Thompson, M.D.

Rathburee, Siam.

### SYRUPUS ACIDI HYDRIODICI.

To the Editor of The Medical Record.

Sir: As the time for revising our National Pharmacopœia is approaching, it may not be amiss to call attention to preparations which, like the above, are useless in the doses usually prescribed. During the course of a recent severe illness the writer had occasion to test the efficacy of syrup of hydriodic acid, and found it wholly inert when taken in doses of twenty to forty minims, as authorized by the dispensatories.

When made after the formula of the United States Pharmacopœia, 1880, each fluidounce of the syrup will weigh 615.3 grains, and will contain 6.15 grains of iodine, equivalent to 8.04 grains of potassium iodide. Therefore, one fluidrachm of syrup of hydriodic acid is equivalent to one grain of potassium iodide. The futility of prescribing twenty- or even forty-minim doses of this preparation must be at once apparent, yet such is the dose as given in the dispensatories.

The Pharmacopœia of 1860 contained a formula for making what was termed "Diluted Hydriodic Acid." This preparation has been omitted in subsequent revisions, because of its unstable character. It is rational to suppose that the "Committee" intended to furnish for the sixth revision a formula for making a preparation of hydriodic acid that would fairly represent the older preparation, minim for minim; as a matter of fact, the old contained ten times more iodine than the new.

While awaiting the appearance of the Pharmacopœia of 1890, let us cherish the hope that the seventh revision will contain a formula for the preparation of a syrup of hydriodic acid of such strength as to be available for therapeutic purposes.

J. F. Golding, M.D.

Brooklyn, N. Y., September 8, 1889.

Safranine a New Reagent for the Detection of Sugar.—A new reagent for detecting sugar in urine has been found in safranine, which is said to possess the advantage of not being decolorized by uric acid, creatinine, chloral, chloroform, peroxide of hydrogen, or the salts of hydroxylamine, all of which reduce Fehling's solution. Albumen, however, does decolorize it. The process recommended is to boil 1 c.c. of the urine with 5 c.c. of a solution of safranine of the strength of 1 in 1,000, and 2 c.c. of a solution of caustic potash. If decolorization is effected the urine is diabetic, normal urine containing too little sugar to decolorize completely so much of the reagent. Chloral and chloroform do attenuate the red color of the safranine, but never completely destroy it. Chloride of barium has been found by Dr. A. N. Hare to act as rapidly as digitalis in slowing the heart, contracting the blood-vessels, and increasing the blood-pressure. He states that it does not act as an irritant poison unless the dose be many times larger than the medicinal one. In five cases of valvular affection of the heart, and two of functional disturbance of that organ, it was found to act beneficially by Dr. Hare.—*The Provincial Medical Journal.*

## Army News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 8 to September 14, 1889.*

WALKER, FREEMAN V., First Lieutenant and Assistant Surgeon. By direction of the Acting Secretary of War the leave of absence on surgeon's certificate of disability granted in S. O. 92, April 20, 1889, from this office, is extended one month on surgeon's certificate of disability. S. O. 211, A. G. O., September 11, 1889. Upon the expiration of his present leave of absence, to report in person to the commanding officer at Jackson Barracks, La., for duty at that station, and by letter to the commanding general, Division of the Atlantic. Par. 2, S. O. 212, A. G. O., September 12, 1889.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 14, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 69 | 15 |
| Scarlet fever | 23 | 2 |
| Cerebro-spinal meningitis | 1 | 0 |
| Measles | 12 | 1 |
| Diphtheria | 64 | 19 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

THE NEW YORK STATE MEDICAL ASSOCIATION will hold its sixth annual meeting at the Hotel Brunswick, Fifth Avenue and Twenty-seventh Street, this city, on September 25th, 26th, and 27th inst. The programme is as follows: *First Day, Morning Session.*—"Inversion of the Uterus, Novel Treatment," "The Latero-dorsal Position in Gynecic Irrigation," by Dr. George E. Fell; "The Treatment of Uterine Fibroids by Electricity," by Dr. Henry D. Ingraham; "Pelvic Cellulitis in Women," by Dr. W. H. Robb; "Report of a Case of Laparotomy for Ruptured Pyo-salpinx: Error in Diagnosis; Recovery," by Dr. C. S. Wood; "The Use and Abuse of the Forceps in Obstetrics," by Dr. J. P. Garrish, all of this State. *Afternoon Session.*—Discussion on "Tubal Pregnancy," in which the following will take part: Drs. William T. Lusk, of New York; William Goodell, of Pennsylvania; George T. Harrison, of New York; Howard Kelly, of Pennsylvania; Theophilus Parvin, of Pennsylvania; Isaac E. Taylor, of New York; T. Gaillard Thomas, of New York; Ely Van de Warker, of New York; W. H. Parrish, of Pennsylvania; and W. H. Wathen, of Kentucky. *Night Session.*—"Prognosis in Pulmonary Phthisis. How much has it been Improved, and by what Means?" by Dr. Avery Segur; "Affections of the Eye, Symptomatic of Disease of the Central Nervous System," by Dr. Alvin A. Hubbell; "A New Portable Accumulator," by Dr. Robert Newman; "The Warming and Ventilation of Public School Buildings," by Dr. Ira B. Read; "A Word in Favor of Free Dispensary and Free Hospital Work," by Dr. E. J. C. Minard; "The Microscope in Diagnosis; Personal Observations," "Forced Respirations; Additional Observations," by Dr. George E. Fell, all of this State. *Second Day, Morning Session.*—"Address on Surgery," by Dr. Francis Bacon, of Connecticut; "Alcoholic Paralysis," by Dr. T. D. Crothers, of Connecticut; "A Few Fads," by Dr. H. D. Didama, of New York; "Some of the Uses of the Transfixion Ligature," by Dr. T. H. Manley, of New York; "The Shadow Line of Insanity," by Dr. John Shrady, of New York. *Afternoon Session.*—Discussion of the "Treatment of Hernia," by Drs. Joseph D. Bryant, William T. Bull, Charles W. Brown, T. H. Squire, William S. Tremaine, William T. Ball, Roswell Park, Charles McBurney, Charles L. Squire, D. M. Totman, Frederick S. Dennis, and John A. Wyeth, all of this State. The points which will come in for a share of attention are the special mechanical treatment, the injection, open and non-open methods, the technique and the best plan of treatment when gangrene of the sac or its contents becomes a complication. *Night Session.*—"Lantern Views," by Dr. Edward K. Dunham, of New York; after which a collation will be served. *Third Day, Morning Session.*—Address on Medicine: "On the Bacteriological Test of Drinking-water," by Dr. Edward K. Dunham, of New York; "The Cure of Hæmorrhoids by Excision, and Closure with the Buried Animal Suture," by Dr. Henry O. Marcy, of Massachusetts; "Report of a Case of Ataxic Paraplegia," by Dr. Darwin Colvin, of New York; "Observations on Dislocations of the Hip," by Dr. U. C. Lynde, of New York. *Afternoon Session.*—Discussion of the "New Hypnotics," by Drs. W. H. Flint, Austin Flint, E. G. Janeway, Charles Rice (Ph.D.), Charles G. Stockton, and John G. Truax, all of this State; "Extraction of Cataract without Iridectomy," by Dr. Charles Stedman Bull, of New York; "Two Cases of Angular Deformity of the Knee-joint," by Dr. Lewis Hall Sayre, of New York. The Committee of Arrangements are as follows: William T. Lusk, *President*, and E. D. Ferguson, *Secretary, ex-officio Members of the Committee;* John G. Truax, *Chairman;* Charles E. Denison, *Secretary;* E. S. F. Arnold, Glover C. Arnold, William R. Ballou, Alfred L. Carroll, John W. S. Gouley, John H. Hinton, Charles A. Leale, J. R. Macgregor, S. B. Wylie McLeod, Augustus D. Ruggles, John Shrady, and Isaac E. Taylor. The presence of the members of the profession is especially desirable.

"ELECTRICITY IN GYNECOLOGY," was the title of a paper read at the recent meeting of the Alabama Medical Association, by Dr. W. E. B. Davis, of Birmingham. He believed that ultra-enthusiasm had led to frequent failure in the use of this remedy, but said there should be no question as to its importance as a therapeutic agent in gynecological practice, when such men as Apostoli, the Keiths, Engelmann, and other competent observers, who have had experience in its application, report most satisfactory results. He advised the use of the current of the Edison circuit, direct from the dynamo when it could be had, thereby avoiding the annoyances and inconveniences of a battery. Great stress was laid on the importance of the application of the faradic current in subinvolution of the uterus. Every woman who had had an abortion or had been confined at full term was placed on ergot, but should there be incomplete involution at the expiration of six weeks, he began at once the use of the faradic current, with the bipolar, intra-uterine excitor of Apostoli, and repeated the application every second or third day until the organ had returned to its normal size, "which can always be counted on with mathematical certainty." Cases were reported to show the value of the faradic current in subinvolution of the uterus, and to illustrate its efficacy in displacements due to the enlarged, hyperæmic condition of the organ following parturition. The current of tension—the current from the long, fine wire—had proven a valuable agent for the relief of pain, and cases showing permanent relief were quoted. To illustrate the power of the faradic current on the perineum, vagina, and uterine ligaments in relieving prolapsus of the uterus, and also the effects of the current in relieving pain, the following case was reported: Mrs. P——, aged thirty five, had last child four years ago; since which time she had suffered almost all the time from pelvic pains, insomnia, and very marked nervous symptoms. The pain was so severe at her menstrual periods that she had been advised by her physician

to have her ovaries removed, and it was for this purpose that the speaker was consulted. The uterus was normal in size, but prolapsed to a marked degree, which was due to its relaxed supports. The bipolar vaginal excitor, with strong current, was used every second or third day for two weeks, and at the next period she did not know when the flow appeared. In eight weeks her uterus remained in proper position; she was relieved of insomnia, and her nervous symptoms improved. Two months after the treatment was stopped she became pregnant. Both the currents of quantity and tension were used at each consultation in this case—the former for the relaxed muscle, the latter for pain. The patient always felt better after each séance. The currents of quantity and tension have been used with very satisfactory results as indicated by Apostoli, but he has begun to use the current of tension not only for pain, but to stimulate relaxed and enfeebled muscle fibre. The current of tension is borne better by the patient, and he has been unable to recognize the superior results of the current of quantity on muscle over the current of tension. In displacements of the uterus he supports the organ with wool tampons, and does not object to any form of pessary, properly fitted, in connection with the treatment by electricity. He believes proper support of the organ, combined with the proper application of electricity, to be the most rational treatment for this condition. When the uterus is enlarged from hyperplasia, the continuous current is indicated. All cases of chronic endometritis are amenable to galvanism—the positive current when there is much leucorrhœa or profuse menstruation, and the negative in other cases. From seventy-five to one hundred and fifty milliampères are used twice weekly for five minutes at a time. The sound is usually introduced through a bivalve speculum, and the handle allowed to rest on a large wad of absorbent cotton, which prevents injury to the endometrium. This is preferred because it permits of more thorough antisepsis, and allows the physician to rest his hand during the operation. He did not claim that electricity would do away entirely with such surgical procedures as shortening the round ligaments —Alexander's operation—or attaching the cornua of the organ to the abdominal wall, or the narrowing of the vagina by the many methods at present in vogue; but he insists that many cases could be relieved by this method of treatment which would otherwise be condemned to the knife. The local application of the faradic current is capable of relieving many cases of amenorrhœa due to atrophy of the uterus. In menorrhagia due to relaxation of muscle, to engorgement, when the patient menstruates from eight to nine days, after a few applications the menstrual periods would only last from four to five days. The positive galvanic current is the remedy indicated for hemorrhage due to a disease of the endometrium, and is the current usually indicated for hemorrhage. Women often become pregnant soon after being treated by electricity, and it is unquestionably a valuable remedy for steriliity due to nervous causes, described by Dr. Campbell. In neuralgic dysmenorrhœa and dysmenorrhœa in women of a hysterical temperament—whom the slightest excitement or worry will cause to suffer greatly—those cases where there is no apparent pathological lesion—he has succeeded, as with no other remedy, by the application of the current of tension or by the mild positive galvanic current. The negative current is indicated when the pain is due to mechanical causes in the cervical canal—and when there are inflammatory deposits around the ovaries, etc. He did not think that galvanism would take the place of the removal of the ovaries and tubes, but said each had its special field, and, should electricity fail, no harm had been done, and the operation could still be resorted to. He said the subject which had concerned the profession most in connection with the use of electricity was the treatment of fibroid tumors, and that the results of the treatment in the hands of Apostoli, the Keiths, Engelmann, Lapthorn Smith, and others, had demonstrated that this is the proper treatment for fibroid tumors, which "offer probabilities of healthy retrograde metamorphosis." He had followed Apostoli's instructions in this class of neoplasms, and believed that the majority of cases could be symptomatically cured. Certainly Apostoli's treatment should be tried before resorting to hysterectomy.

The Sensibility of Telegraphers.—The following incidents are from an interesting illustrated paper by Dr. J. Emmet O'Brien, of this city, in *The Century* for September, on "Telegraphing in Battle." "In Butler's advance on the Petersburg & Richmond Railroad, May 7th, a line was carried along with the column to within sight of that road, and worked until Beauregard struck us at Drewry's Bluff, on the 16th, when General Butler ordered his chief operator to 'bring the line within the intrenchments.' In these trenches one night Maynard-Huyck was awakened from sleep, not by the familiar voice of his instrument, but by the shriek of a Whitworth bolt, a six-pound steel shell, which passed through the few clothes he had doffed, then ricochetted, and exploded beyond. Congratulating himself that he was not in his 'duds' at the moment, the boy turned over and slept through the infernal turmoil of an awakening cannonade until aroused by the gentle tick of the telegraph relay. We used no 'sounders' in those days at the front. In illustration of the sensibility of hearing acquired by the military operators for this one sound, the writer may be pardoned another personal incident. At Norfolk, in April, 1863, he happened to be alone in charge of the telegraph when Longstreet with a large force laid siege to Suffolk. In the emergency he remained on duty, without sleep, for three days and nights, repeating orders between Fort Monroe and the front. Toward morning on the third night he fell asleep, but was aroused by the strenuous calls of the fort, and asked why he had not given 'O. K.' for the messages just sent. He replied that none had been received. 'We called you,' said the operator at the fort; 'you answered, and we sent you two messages, but you failed to acknowledge them.' The despatches were repeated and forwarded, when, on taking up a volume of Scott's novels, with which he had previously endeavored to keep awake, the writer was astonished to find the missing telegrams scrawled across the printed page in his own writing, some sentences omitted and some repeated. It was a curious instance of somnambulism."

The Mystery of Pain.—The philosophy of pessimism, associated with the names of Schopenhauer, Hartmann, and Leopardi, owes its influence in no small degree to the depressing relations which a resolute contemplation of the vast amount of suffering and sorrow in the world is apt to excite in some minds. The universality of suffering and disappointment; the wide prevalence of disease; the ubiquity of pain; the frustration of effort; the general admission that the present is unsatisfying, and that only the hope of a better future for the individual and the race keeps energy alive; the confession that "man never is, but always to be blest"—such reflections suggest a basis for pessimism, and explain, if they cannot justify, its hold over many minds of a superior order. But, happily, the pessimistic logic contains one rather obvious fallacy, which robs it of much of its cogency. It accentuates evil and suffering, but omits to take account of the benefits to humanity of which they are indirectly the source and the occasion. The more we reflect upon the subject, the more convinced shall we be that pure, unmixed, unredeemable evil hardly exists, and that some compensation can be found or created in connection with the direst calamity. The hurricane seems the embodiment of destructive and maleficent activity; but if in its train are found ruin and death, there also may we discover a purified atmosphere, the arrest of disease, and the descent of fertilizing rain. When cholera sweeps over wide regions with its pestilential breath the scene is one of destruction, death, despair; but how great the benefit to unborn generations if such a calamity tends to the more careful study and more systematic application of the laws of hygiene. Pain

itself, the most universal of evils, has a side the contemplation of which lends no countenance to pessimism. On this side we shall look for a moment or two. In the first place, pain obviously plays a great part in the preservation of life. If fire did not cause pain in burning, if the knife could pierce the flesh without suffering, if the noisome gas caused no inconvenience to sense or brain, it is difficult to see how, with our present organization, life could be long preserved. We should be constantly courting death, and should remain in ignorance of danger until the mischief effected was irremediable. The child who burns its hands, or cuts its finger, or knocks its head against a table, or swallows some noxious mess, suffers, indeed, but, from another point of view, may be more truly said to be learning invaluable lessons of self-preservation. Probably this, although a painful way, is the only one in which such knowledge could be acquired. In spite of the fact that experience is such a stern instructor and punishes so promptly, it is one of the most common of commonplaces that we are slow to profit by its admonitions, and only learn wisdom after repeated warnings. The pain that follows a breach of Nature's laws may not always follow so quickly upon error as in the cases just cited, but not the less is it salutary. The malaise that follows excessive intellectual effort or a drunken debauch is Nature's admonition that her rule cannot be set at defiance with impunity. The persistence in any course of life, any habit, diet, or occupation inimical to health, is always attended by warnings—at first few and faint, but by degrees more frequent and peremptory —that Nature is being outraged, and that her vengeance will not tarry long. Such warnings are painful, but plainly they tend to the good of the individual and the preservation of the race. The uses of pain are, however, by no means wholly, perhaps not even chiefly, physical. Pain is the great teacher, the great agent in the development of character. It may be doubted whether any of the nobler virtues—self-sacrifice, self-knowledge, courage, patience, tolerance—ever have been, or ever can be, fully developed without the agency of pain. It is those who have suffered who are strong. It is he who has borne pain in his own person who best knows how to relieve, or to sympathize with, the suffering of others. Thus the pain of the individual becomes the fountain of help and consolation to the species. The sorrow of one becomes transmuted into the joy of many. There are also benefits arising from pain which are reflex or vicarious in character. It not only strengthens and purifies the sufferer, but it develops the helpfulness and sympathy of those upon whom he is dependent. Oliver Wendell Holmes beautifully remarks that the long, anxious, arduous tendance upon a sick friend whitens the hair, but also whitens the soul. There is consolation in the reflection that, if sickness and suffering increase the cares and responsibilities of others, there may arise compensation where it is least looked for. It is one of the most pleasing traits of human nature, that we seem naturally to be most bound to those for whom we have suffered most. The mother loves her child not less but more because she suffered in bringing it into the world, and because her only anxiety on its behalf partakes often of the nature of pain. No careful thinker will pretend that the above considerations fully explain "the mystery of pain." It remains a mystery in some respects still; but such reflections tend to lighten its darkness, and to suggest that in ways not yet evident the sorrowing and suffering of the world may be working out the world's regeneration.—*The Lancet.*

THE TREATMENT OF OZÆNA WITH GLYCERINE.—At a recent meeting of the Society of Military Surgeons in Vienna, Dr. Sidlo strongly recommended the treatment of ozæna with glycerine. His method consists in daily washing out the nasal cavity with a two per cent. solution of chloride of potassium, to which ten per cent. of glycerine has been added. This is followed up with the insertion of rolls of cotton soaked in a mixture of one part of glycerine and three parts of water, the tampons being allowed to remain in place for an hour at a time. Using this method, he claims good success in the management of ozæna. The method requires some weeks to effect a cure; but no one who has treated ozæna often will think a few weeks too long to devote to any method which is likely to be successful. The one proposed by Dr. Sidlo is so simple, and apparently so rational, that it certainly seems worthy of further trial, and if other medical men can cure such cases as he has cured in this way, it will be a very useful addition to our therapeutic resources.—*Medical and Surgical Reporter.*

OLD PRIMIPARÆ.—Dr. Truzzi, of Milan, has studied the statistics of a lying-in hospital in that city from 1852 till last year, with a view to ascertain the truth of certain statements respecting first labors comparatively late in life. Most of these statements, familiar to readers of obstetric manuals, were confirmed. The rate of morbidity was found much higher than in younger primiparæ. This fact was ascertained, so far as Dr. Truzzi's cases were concerned, to be due in the majority of cases to renal disease. Puerperal convulsions were found to be more frequent than in younger subjects. A slight degree of contraction of the pelvis caused far more trouble than in more youthful cases. The period of dilatation of the os was long; lacerations of soft parts frequent. Instrumental labor was very often necessitated, especially the forceps, which had frequently to be applied to remedy simple uterine inertia. —*British Medical Journal.*

VENTILATION IN ICELAND.—The extreme cold of the winter in Iceland reduces the system of domestic ventilation in that country to very primitive principles. A traveller there was so choked one night by the close atmosphere of the air-tight little chamber in which he slept, with all the male members of the family, as to be compelled to wake his host, who sprang out of bed at the call, pulled a cork from a knot-hole in the wall for a few minutes, and then, replacing the cork with a shiver, returned to bed.—*College and Clinical Record.*

GUM-CHEWERS' PARALYSIS is the latest form of professional neurosis recorded in medical literature.

FREEDOM OF AIR FROM GERMS.—Dr. Le Fort says that microbes are never conveyed in the air, but only by contact with the fingers, instruments, etc.

SALT IN MILK.—Jacobi recommends the addition of common salt to milk for infants, as it prevents the coagulation in large masses.

COAL-OIL IN INTUSSUSCEPTION.—Dr. Whitney, of Davenport, Washington, reports two cases of intussusception relieved by enemata of coal-oil.

LOCOMOTIVE ENGINEERS are inclined, it is said, to obesity.

FRECKLES are said to be readily removed by a lotion composed of equal parts of lactic acid and glycerine.

SULPHONAL is recommended as an almost unfailing remedy against night-sweats.

DEAD DOGS FOR MEDICAL STUDENTS.—Some medical students having asked the Mayor of New York to allow them a certain number of condemned dogs from the pound, for experimental purposes, that functionary, as the newspapers report, has duly considered the request, also the protest of a certain humane person who dreads the cruelty to which the dogs might be subjected by the students, and has come to the conclusion that he will allow the students a supply of dead dogs, but no live ones. This generosity is about equal to Artemus Ward's, as exemplified in his answer to a person who had asked the privilege of seeing his show without paying: "No, you can't go in without paying, but you can pay without going in."—*The New York Medical Journal.*

### CHRONIC ENDOCARDITIS.[1]

BY FRANCIS DELAFIELD, M.D.,

NEW YORK.

IT is proper that I should offer to you some reason for selecting so ordinary a disease as is chronic endocarditis as the subject for this paper. But the ordinary diseases are, after all, the important ones, and often as we see them we never really know them well enough. Any fresh record of facts, any new way of grouping or of looking at these facts, must be of some little service. It is the object of this paper, therefore, not to give a systematic account of endocarditis, but to draw attention to some features of the disease; not to give a history of the views of other observers, but to state simply what I have put together from my case-books and post-mortem records.

Of the ordinary diseases few are more common than is chronic endocarditis. In few of them is there so great a variety in the severity of the symptoms. From the condition of a trifling inconvenience to that of a distressing and fatal disease there seems to be no limit to its various phases. We constantly meet with patients whose heart-valves are seriously damaged, and who yet enjoy good health; can follow laborious occupations, and are often ignorant that they have any disease. On the other hand, we, with equal frequency, see patients in whom the same valvular lesions are attended with the most serious symptoms and with death. It is, therefore, a matter of practical importance to determine, as accurately as we can, why it is that some of these patients do so well and others so badly. For it is in this way that we are most likely also to determine a rational treatment for the disease.

It seems evident that nearly all the most important symptoms of chronic endocarditis are due to the disturbances produced in the distribution of the blood throughout the body. It is by these disturbances of the circulation that the cerebral and pulmonary symptoms, the loss of nutrition, and the dropsy are produced. The problem before us, therefore, is to determine why in some cases of chronic endocarditis there are disturbances of the circulation, and why in other cases there are not. It might seem at first that the solution of this problem is an easy one, that the disturbances in the circulation are simply in proportion to the stenosis or insufficiency of the valves. A very moderate experience, however, is sufficient to show that this is not the case. The problem is a complicated one, and the disturbances of the circulation are due to a number of causes which act singly or together. We may enumerate these causes as follows: The endocarditis; the dilatation and hypertrophy of the ventricles; the inflammation or degeneration of the walls of the heart; the inflammation of the coronary arteries; the abnormal heart-action; the associated pulmonary emphysema, chronic endarteritis, and chronic Bright's disease.

To follow out the mode of action of all these causes is not possible in a paper of this character. I confine myself to the consideration of three of them—the endocarditis, the abnormal heart-action, and the secondary and complicating changes in the kidneys. Not that the others are unimportant, but that these three are perhaps the most important of all.

[1] Read before the meeting of the American Medical Association, June 26, 1889.

1. *The Endocarditis.*—In thinking of persons with valvular lesions we must remember that some of these persons, while under our observation, are suffering from chronic endocarditis, and that some are only suffering from the changes produced in the valves by an endocarditis which no longer exists. In the one case they suffer from a chronic inflammation; in the other, from a deformity. It may be indeed that such a deformity leads to progressive changes in the cavities and walls of the heart. But this is much less likely to happen than if the changes in the valves are also progressive.

Chronic endocarditis may directly follow acute endocarditis; it may be developed after a long interval in valves damaged by an old attack of endocarditis; it may from the first be a chronic lesion. We find, especially in children, an uninterrupted history of cardiac symptoms beginning with an acute attack and continuing as a chronic disease for years. We find in older persons, with marked cardiac symptoms developed late in life, a history of an acute endocarditis in childhood from which they had apparently recovered. We find in adults the gradual development of one cardiac symptom after another, so slow and so gradual that we can hardly date the beginning of the disease.

Chronic endocarditis, when it has once commenced, seems to have a natural tendency to persist and to involve other portions of the endocardium. The cases vary as to the activity of the endocarditis and the intermissions in the course of the inflammation. It is apparently possible for the endocarditis to stop at any time, and the valves will then undergo no further change.

Chronic endocarditis is a productive inflammation, with the formation of new tissue, but without exudation. In its most active form there is a very considerable growth of cells, and also a death of cells, so that the inflamed endocardium is thickened in some places, ulcerated in others, and on the roughened surfaces thus made thrombi are formed. This is the most active and dangerous form of the disease. In its more chronic form the growth of cells is not as great, the cells do not die, the basement substance is thickened. Although the surface of the endocardium is somewhat roughened, and small vegetations are often formed, there are no thrombi. In either form of inflammation there may be added degeneration or calcification of the inflamed endocardium and of the thrombi. It may very well happen that the patient, after suffering from the chronic form of endocarditis for years, may then develop the more active form in the same valve, or in one of the other valves. In the more active form of the disease a large number of the cases run their course within six months from the time of the commencement of their symptoms. A considerable number do not live longer than six or seven weeks. The symptoms are pronounced: Disturbed heart-action; delirium, convulsions, paraplegia; cough, hæmoptysis, dyspnœa; nausea and vomiting; dropsy; loss of flesh and strength, and anæmia, and a rise of temperature. These patients are apt to get rapidly worse, but there may be intermissions, and the inflammation may stop altogether. It seems evident that in the treatment of these patients we must remember that they are suffering from an inflammation of some activity, and that rest in bed, the use of cold or of counter-irritation over the heart, are measures likely to be of use. On the other hand, in the slow form of endocarditis the disease lasts for many years. There are usually intermissions in its course, and it may stop altogether at any time. Many

of the patients have no symptoms. In those who do, some one symptom is first developed, and then, as the disease progresses, others are added. These patients are regularly better for an out-of-door life, with as much exercise as they are able to take.

2. *The Abnormal Heart-action.* — It is possible for a chronic endocarditis to run its entire course with a perfectly regular action of the heart. This, however, is the exception. The rule is that the heart's action is disturbed, and this disturbance is often the most important feature of the disease, and furnishes the principal indication for treatment. Such a disturbance of the heart's action may be due to :

*a.* The endocarditis existing as an inflammation of some activity and producing changes in the heart's action in the same way as does an acute endocarditis.

*b.* Such a degree of stenosis or insufficiency of the valves as will mechanically interfere with the heart's action. This often does not become a factor of much importance until the stenosis or insufficiency is well marked, and for this reason it is easy to be deceived as to the character of the lesion.

*c.* Dilatation and hypertrophy of the ventricles are often present, and certainly have their effect in changing the character of the heart's action.

*d.* Chronic myocarditis and disease of the coronary arteries produce the most extreme and intractable disturbances of the heart's action. Fortunately they are not very common.

*e.* Contraction of the smaller arteries throughout the body, with increase of arterial tension and venous congestion.

This condition, although a frequent complication of endocarditis, nephritis, endarteritis, and emphysema, and occurring as an independent condition in some cases of angina pectoris, is yet something concerning which our knowledge is imperfect. Whether contaminated blood irritates the arteries, whether the nervous centres are irritated by contaminated blood, or in what way the contraction of the arteries is produced, we do not know. But such a contraction is produced, and lasts for hours, days, or months. The same patient may never have but one such attack, or he may have many. In patients who have had many attacks the muscular coat of the small arteries is thickened. Such a contraction of the arteries at once changes the character of the heart's action. It becomes rapid, forcible, feeble, or tumultuous. The degree of the cardiac disturbance is apparently in proportion to the degree and suddenness of the contraction of the arteries, but is not related to the severity or extent of the endocarditis. In the early stages of endocarditis we very often see patients who complain of nothing but dyspnœa on exertion and on lying down, and of precordial pain. Otherwise they feel perfectly well and have normal urine. We find the heart enlarged, its action rapid and forcible, and a murmur indicating disease of one of the valves. The radial pulse is distinctly tense. If by treatment the arteries are dilated the dyspnœa disappears, the heart's action becomes natural, and the patients feel well. Or in further advanced and progressing endocarditis we may follow patients for years, who in spite of their endocarditis feel well except when they have attacks of contraction of the arteries. When they have such an attack, dyspnœa and other symptoms are developed and continue for weeks or months. Then, as the attack subsides, the symptoms disappear, and the patients feel well. The first attacks yield readily to treatment. But as time goes on the attacks are more frequent and more obstinate. The pulse is tense, but small. The heart's action is no longer forcible, but feeble or tumultuous. Occasionally we see patients who go on with a chronic endocarditis for many years, but with few or no symptoms. Then, with a slight pleurisy, or pericarditis, or without discoverable cause, a sudden, extreme, and intractable contraction of the arteries is established, causing the most urgent dyspnœa, and continuing up to the time of the patient's death. These attacks of contraction of the arteries are at first readily relieved by the drugs which dilate the arteries—nitrate of amyl, chloral hydrate, nitro-glycerine, opium, and potassium iodide. The patients do well with an out-of-door life and regulated exercise. But as the endocarditis advances and the valves are more damaged, especially by stenosis, these attacks are less readily relieved, and it becomes necessary to keep the patients more and more quiet.

*f.* Unknown causes, which apparently act through the nerves which regulate the arteries of the heart. These form a large, important, and obscure group of cases. In some of these cases the abnormal heart-action is associated with advanced disease of the valves, and it is only by the results of treatment that we can discriminate how much of the disturbance of the heart's action is due to the valvular lesion, and how much to nervous influences. The pulse is of low tension, feeble, and rapid. The heart's action is feeble or exaggerated. The condition of the patients is often very bad, and yet in some of them very marked improvement is obtained by treatment. These patients at first require complete rest, then massage, and later regulated exercise. The most efficient drugs are digitalis, strophanthus, caffein, convallaria, and barium chloride. The heart seems to be always really a weak heart, even though its action is exaggerated. It is often natural to believe that there is degeneration or inflammation of the walls of the ventricles, but yet after death no such changes are found. In other cases the endocarditis is not advanced, the valves are but slightly narrowed or insufficient, there is little or no change in the size of the heart. The heart's action is rapid, either feeble or exaggerated. The pulse is soft and rapid. The patients often have pain or abnormal sensations referred to the heart; the general health may be very much impaired. Although these patients have endocarditis, yet it is really the abnormal heart-action which makes them ill and calls for treatment. Some of these patients are very easily managed, the heart's action soon becomes normal, the pain disappears, and the patients feel well, although the lesion of the valve still exists. Some of them, on the contrary, do not improve. The disturbance of the heart's action and the other symptoms continue, but yet the patients do not die, nor get worse beyond a certain point. There are, however, occasional cases in which the heart's action becomes very bad, and the patients become very feeble and die. After death we find but moderate changes in the valves, and no changes in the walls of the heart. The management of these cases is apt to be difficult. Attention to the diet, the general health, the habits, the climate, the exercise, is of especial importance. Of drugs one or other of the cardiac stimulants is often indicated.

3. *The Secondary and Complicating Changes in the Kidneys.*—Of the persons who suffer from chronic endocarditis a large number never have any complicating disease of the kidneys. In the persons who die from endocarditis it is rare to find normal kidneys. In judging of the frequency of the kidney lesions the most certain criterion is the autopsy. During life it is not sufficient to examine for albumen and casts, which are often absent, but the quantity of the urine, its specific gravity, and the proportion of urea to the ounce of urine must also be determined. Advanced changes in the kidneys often exist in patients whose urine is said, after a superficial examination, to be normal.

In persons who die from chronic endocarditis we find : Chronic congestion of the kidney; chronic degeneration of the kidney; chronic nephritis.

1. *Chronic Congestion of the Kidney.*—The kidneys are of medium size, or large. Their weight is increased, they are hard, uniformly congested, their surfaces are smooth. The epithelium of the cortex tubes is opaque, flattened, or swollen. The glomeruli show a dilatation of the capillaries, with more or less thickening of their walls, and swelling of the cells which cover their walls. In the stroma there is nothing but some exaggeration of the subcapsular areas

of connective tissue, which are found in normal kidneys. The arteries are normal, the pyramid veins are congested, and sometimes dilated. The urine is diminished in quantity at the times when the heart's action is bad, and returns to the normal when it is better. It is apparently never increased, except from accidental causes. The specific gravity is usually between 1.020 and 1.025, but may for a time be down to 1.010, or up to 1.035. The quantity of urea is rarely less than ten grains to the ounce, it may be as high as twenty-one grains. The specific gravity and the quantity of urea must be judged by examining the urine of twenty-four hours, for several days, with the proper allowance for diet and exercise. Albumen and casts are absent, or present in very small quantities. The effect of the congestion of the kidneys on their functions is simply to diminish the quantity of urine. The quality of the urine is good, and the exudation from the vessels amounts practically to nothing. Apparently the only way in which this lesion of the kidney can add to the symptoms of the endocarditis is by diminution in the quantity of the urine.

2. *Chronic Degeneration of the Kidney.*—The kidneys are considerably increased in size and weight, weighing together from sixteen to twenty ounces. Their surfaces are smooth; the cortical portion is thickened, of pink or white color; the pyramids are red. The gross appearance is that of the so-called large white kidney. The epithelium of the cortex tubes is swollen and opaque. In the glomeruli there is dilatation of the capillaries and swelling of the tuft-cells. There are no changes in the stroma, or in the arteries; the pyramid veins may be congested. The quantity of the urine varies with the changes in the action of the heart, sometimes abundant, sometimes scanty, sometimes suppressed. The specific gravity is not diminished, nor is the proportion of urea to the ounce decreased. Albumen and casts in small quantities are more frequently present than with chronic congestion. While it is difficult to separate the kidney symptoms from the heart symptoms, yet one has the impression that this kidney lesion is more serious than chronic congestion, and has its effect in increasing the symptoms of the endocarditis, especially the loss of nutrition and the anæmia.

3. *Chronic Nephritis.*—A chronic inflammation of the kidneys may follow chronic congestion or chronic degeneration; it is then evidently a direct result of the endocarditis; or it may be developed as an independent inflammation, and is to be regarded as an associated, and not a secondary, lesion.

*a.* Chronic nephritis following chronic congestion of the kidneys. The kidneys remain increased in size, or become somewhat smaller. The capsules are adherent, the surface of the kidney is finely nodular, the consistence of the organ remains hard, and the general venous congestion continues. The epithelium of the cortex tubes is opaque, swollen, or flattened. The tubes may contain coagulated matter. The straight tubes of the cortex and pyramids may contain cast matter. The capillaries of the glomeruli are swollen, their walls are thickened, there is an increase in the size and number of the cells which cover the capillaries. There is a considerable growth of connective tissue in the stroma, distributed according to the arrangement of the normal subcapsular wedges. Within these masses of new connective tissue the tubes and glomeruli are atrophied. The walls of the arteries may be thickened, the capillary veins in the cortex may be dilated and their walls thickened. The quantity of the urine varies very much at different times in the same patient; sometimes it is above, sometimes below the normal. The specific gravity falls to 1.020 or 1.016. The proportion of urea to the ounce is somewhat diminished. Albumen and casts in moderate quantities are regularly present at some time in the course of the disease, but during much of the time they are entirely absent. The patients seem to be especially liable to spasmodic dyspnœa and to loss of flesh and strength.

*b.* Chronic nephritis following chronic degeneration of the kidney. The kidneys are large, their surface smooth, the cortex thick and white, the pyramids red. The epithelium of the cortex tubes is opaque, flattened, or swollen. The convoluted tubes contain coagulated matter, the straight tubes cast matter. The capillaries of the glomeruli are dilated, and the cells covering the capillaries are swollen. There are no changes in the arteries. The quantity of urine varies at different times; often it is very scanty. The specific gravity keeps close to the normal, or may even be above it. The proportion of urea to the ounce of urine is not diminished. Albumen is regularly present in considerable quantities; casts are somewhat less constant. The patients who have this form of nephritis are apt to exhibit the anæmia and dropsy in a very marked degree, and to get worse rapidly.

*c.* Chronic nephritis associated with chronic endocarditis, but apparently not caused by it. Such an association of chronic nephritis with chronic endocarditis is of very frequent occurrence. Either one of the lesions may be developed the first, either one may be of the most importance. In all of these cases, while there is much variety in the gross appearance of the kidneys the changes in structure are much the same. The epithelium of the cortex tubes is degenerated; some of the glomeruli are converted into fibrous tissue, in others there is only a growth of the tuft-cells; there is a considerable growth of connective tissue in the stroma; the walls of the arteries are thickened. There are, however, two points in which these kidneys differ from each other: the quantity of exudation from the blood-vessels and the rapidity of the changes in the kidney. To these two points of difference correspond the differences in the clinical histories. We may, therefore, for clinical purposes, distinguish three forms of chronic nephritis.

1. Chronic nephritis, with a large and continued exudation of serum from the blood-vessels of the kidney into the tubes. The urine is sometimes diminished, sometimes very much increased in quantity. The specific gravity is lowered, often about 1.016. The proportion of urea to the ounce of urine is diminished. The urine constantly contains considerable quantities of albumen and numbers of casts. The patients do badly. Dropsy, anæmia, loss of flesh and strength, and chronic uræmia are the regular symptoms.

2. Chronic nephritis, with moderate and intermittent exudation from the blood-vessels. The urine is more or less increased in quantity, except when the patient has an attack of contraction of the arteries; then it is diminished. The specific gravity is lowered. The proportion of urea to the ounce of urine is diminished. During much of the time no albumen or casts are present, but from time to time, when the patient is doing badly in other ways, they appear in moderate quantities. These patients usually live for a number of years, slowly getting worse. They are especially liable to attacks of contraction of the arteries, with dyspnœa, headache, sleeplessness, and convulsions.

3. Chronic nephritis, with little or no exudation from the blood-vessels, the nephritis advancing very slowly. These kidneys are considered by some authors to be examples of fibroid degeneration rather than of chronic inflammation. The urine shows no change, except that the specific gravity and the proportion of urea, from year to year, are gradually lowered. Some of the patients never have any renal symptoms; some of them have attacks of contraction of the arteries; some of them simply lose some flesh, and a great deal of strength, and die quietly.

---

Salicylic Acid in Tonsillitis.—Dr. Haberkorn, writing in the *Centralblatt für Chirurgie* for August 10, 1889, recommends the local use of salicylic acid in tonsillitis, whether simple or diphtheritic. He uses the dry crystals, applying them by means of a throat-brush. This causes no irritation, he says, but the salicylic acid, dissolving gradually, exerts a continuous antiseptic action.

## COLON-FLUSHING IN TYPHOID FEVER.[1]

By A. P. BUCHMAN, M.D.,

FORT WAYNE, IND.

If, in a considerable number of cases of typhoid fever, who all suffer from the same fundamental lesions, present nearly, if not quite, a typical temperature-curve, and altogether run about the same course, and, including environments, receive the same treatment, one observes an amelioration of symptoms that can be safely credited to the *particular* course of treatment instituted and kept up all through the time of high-temperature manifestations, and, in a modified degree, during the period of convalescence, it will, I hope, serve the purpose for which this paper was written, viz., to call attention to the mode of treatment, to present the history of one of the cases.

On July 19th I was asked to prescribe for Mr. W——, aged about fifty, by his wife, she describing a case of simple intermittent malarial fever. I sent him a prescription composed chiefly of quinine, and heard nothing more of the patient until the evening of July 22d, a little more than three days having elapsed, when word was sent for me to call and see the patient. I saw him at 8.30 P.M., and found a temperature of 105° F., tongue red at tip and edges, centre dry and shining, some gurgling in the iliac fossæ, slight tympanites, and some half-dozen thin and rather offensive bowel-discharges during the day just passed; a general tired feeling, some headache, and such other symptoms as go to make up the typical typhoid condition. In addition to this there was acute mental worry, owing to unpleasant business complications. After prescribing and leaving general directions for the night, I left the house in no very pleasant frame of mind. Very acute, almost stinging, mental worry, and a typhoid fever under headway for five days, with the subject working at his desk and on his feet all of this time, was, to say the least, a very disagreeable foreshadowing. I called again next morning, at nine o'clock, when the temperature was 103.5° F., tympanites much increased, some delirium, and very offensive bowel-discharges. This day was passed with extreme restlessness, and at my evening visit the temperature had gone up to 105.8° F., small, thready pulse, very rapid, bowels greatly distended with gas, and so much delirium that it was necessary for someone to remain at his bedside constantly. Just what to do next was a problem that presented itself for immediate solution.

I concluded to wash out the colon with a large enough quantity of water to thoroughly cleanse it, and to this end procured a fountain-syringe of two-quart capacity; filling the reservoir with water directly from the hydrant, to which I added two ounces of listerine, I proceeded to fill the colon.

After waiting a few minutes, the patient was assisted on the commode; the entire contents of the colon were easily passed, thus relieving the ileo-colic valve, and permitting the accumulated gas in the small intestines to pass away as well. The odor accompanying this discharge was simply vile. The patient was now returned to the bed, and I passed my hand over the abdomen to note the condition. I found it flat and soft, all of the distention gone. Within the succeeding forty minutes his temperature had dropped to 101.4° F., the skin became moist, and before I left the house he had fallen into a quiet, peaceful sleep which lasted, with one or two slight interruptions, the whole night. At this point I dropped all drug medication, save a one-grain dose of quinine, three times a day, and substituted colon-flushing. Every time the temperature approached 103° F. the colon was thoroughly flushed, which was from one to three times every twenty-four hours. From July 26th to August 8th there was seemingly gradual but steady approach to the health-level. I say seemingly, for on the morning of August 9th, at four o'clock, I was hastily summoned to the patient. The messenger stated that for an hour previous there seemed to be a great change for the worse. On arriving at the bedside I found the bowels rather distended, the breathing labored and slow—abdominal. My patient was in a state of shock nearly profound, resulting from, as I believed, intestinal hemorrhage. Until 3 A.M. everything had been quiet and favorable. Twice during the night he had taken nourishment with evident relish, but suddenly at this hour the whole scene changed, and they thought the patient dying. I immediately washed out the colon with hot water, first, for its stimulating effect, and, second, to relieve the bowels, as no blood had been discharged. Very soon the water, very bloody, came away, and soon I had the satisfaction of seeing the patient rally, and in less than two hours he seemed as well as he had been at any time the preceding day. From now on he convalesced rapidly. The colon-flushing was continued unremittingly, from one to three times every twenty-four hours, until the period of convalescence had ended, which was, to me, a surprisingly short one. I saw the patient last on the morning of August 20th, when he was moving about the room, and was gathering strength rapidly.

On July 20th I began to use the same method of treatment on a series of five other cases of typhoid fever, giving no drug save one- or two-grain doses of salicylate of quinine three times a day. They have all progressed very favorably, and at this time (August 27th) I have so treated a total of thirteen cases. I wish to add here that at no time did I neglect to have a cold sponge-bath given at least once every twenty-four hours. The diet was chiefly milk.

In summing up, I find the situation about as follows:

1. That from one to three quarts of cold water can be easily and safely passed into the colon, which will rapidly lower a high temperature.
2. That I believe, in some of the cases, the water passed the ileo-colic valve, entering the small gut.
3. That tympanitic distention will always disappear with passing away of the water so injected.
4. That putrefactive fermentation of the bowel-contents is prevented by such use of water.
5. That toxic substances are more rapidly absorbed by the cæcum than by any other portion of the intestinal canal, and that, by a judicious and careful washing with antiseptic water, we can prevent the absorption of such toxic substances, and prevent and modify general systemic poisoning.

August 27, 1889.

Misapplied Ingenuity.—An Indian contemporary narrates some curious instances of misapplied ingenuity on the part of certain habitual criminals in that country. The discovery on a prisoner of a heavy leaden bullet, about three-fourths of an inch in diameter, led to an inquiry into the object to which it was applied. It was ascertained that it served to bring about the formation of a pouch-like recess at the base of the epiglottis. The ball is allowed to slide down to the desired position, and it is retained there for about half an hour at a time. This operation is repeated many times daily until a pouch of the desired size results, in which criminals contrive to secrete jewels, money, etc., in such a way as to defy the most careful search, and without interfering in any way with speech or respiration. Upward of twenty prisoners at Calcutta were found to be provided with this pouch formation. The resources of the professional malingerer are exceedingly varied, and testify to no small amount of cunning. The taking of internal irritants is very common, but would-be in-patients very frequently overshoot the mark and render recovery impossible. Castor-oil seeds, croton beans, and sundry other agents are employed with this object in view, and the medical officers of Indian prisons have to be continually on the lookout for artificially induced diseases which baffle diagnosis and resist treatment. Army surgeons are not altogether unfamiliar with these tricks, but the British soldier is a mere child in such matters compared with the artful Hindoos.—*Medical Press and Circular.*

## RHEUMATISM OF THE OCULAR MUSCLES.[1]

By JOHN W. WRIGHT, M.D.,

COLUMBUS, O.

ALTHOUGH some particular parts of the body are more disposed to acute rheumatism than others, yet it cannot be denied that all fibro-muscular structure, wherever found, is more or less liable to this affection; and the same cause that will produce it in the muscular tissue in one part of the body is liable to affect this tissue similarly, wherever found.

That persons of rheumatic diathesis do frequently suffer from rheumatism of the fibro-muscular structures of the eye and its appendages, there cannot be a doubt.

That the optico-orbital muscles, as well as the ciliary muscle and the iris, are subject to both the acute and chronic types of the disease, is evident, especially when the patient is possessed of the rheumatic habit.

I believe that iritis, when not traumatic or specific, is generally rheumatic. The same may be said of cyclitis, and perhaps choroiditis. One thing we know full well, that these affections are liable to follow acute attacks of rheumatism, and are liable to attack persons of rheumatic diathesis.

It is not my desire to enter into a discussion of the pathogenesis of rheumatism here; although the general pathology which considers it a blood disease may be regarded as correct, we have never been able to explain by it the symptoms of an acute attack, where, in addition to the constitutional disorder, we have local pain, occasional heat, redness, and swelling, with febrile symptoms; for it is not shown that exudation occurs, or that it is followed by the usual results of that condition.

If there is effusion in acute rheumatism, which is doubtless true, I do not pretend to offer a solution as to its disposal, but one thing is quite sure, that in iritis following rheumatism, or what we are pleased to call rheumatic iritis, there *is* effusion of plastic or serous matter, which frequently plays an important part in the futurity of the eye.

Owing to the structure of the eye, the iris being prominently exposed to view, this exudation is readily seen, and the inflammatory process can be carefully watched; while in other parts of the body the muscular structures are covered and hidden from view by the integument, the connective, and often other muscular tissue.

As this paper has to do with rheumatism of the ocular muscles, we shall proceed to the symptoms preceding and accompanying this affection.

There is generally, at the inception of the affection, constipation, a dry, heavily coated tongue, and a foul breath, accompanied by headache and insomnia; then chills followed by fever, the increase in temperature being usually from one to four degrees.

Like acute rheumatism affecting other parts, rheumatism of the ocular muscles often seems to follow a certain regular and migratory propensity in its attacks, first visiting the muscles of one eye, then those of the other. Often the muscles of one eye alone may become affected, but most frequently those of both. The ocular muscles only may be affected, but generally other parts of the body are at the same time similarly acted upon. I have frequently noticed patients complain of pain in one knee, which, in a short time, would be transferred to the other, then to some other joint, as the ankle, then again to the other; then again, as before mentioned, to the ocular muscles.

Another interesting fact is that while there is pain in the joints there is usually none in the region of the eyes, and *vice versa*. As in acute rheumatism the joints are sometimes swollen and red, and the connective tissue in their region infiltrated, so also the conjunctiva and the connective tissue in the region of the ocular muscles become œdematous, and in some cases there is severe conjunctivitis and chemosis. As in ordinary rheumatism there may be severe pain with very little tenderness or swelling of the joints, so in the rheumatism of the ocular muscles there may be no conjunctival irritation nor infiltration of the connective tissue in the region of the affected muscles, nevertheless the pain is quite severe.

Sometimes all of the ocular muscles are affected, frequently but one or two. This can be readily determined by making pressure upon the closed lids, and the affected muscles thus located, the patient complaining frequently upon the slightest pressure over the affected muscle.

The migratory and systematic order in which acute rheumatism often affects the joints, is again evidenced in rheumatism of the ocular muscles. When the internal rectus of one eye is thus affected and there is a metastasis to the other eye, the internal rectus is the one generally to suffer. When all of the muscles of one eye are affected, the transfer affects those of the other alike. When but one or two of the ocular muscles become rheumatic, there is usually but little or no conjunctival irritation; but when all of the muscles are involved, there is always conjunctivitis with more or less infiltration of the connective tissue, and frequently much chemosis. In some cases of the affection there is excessive hyperæmia of the ocular and palpebral conjunctiva, the blood-vessels being engorged with a superabundant lachrymation, presenting the characteristics of catarrhal conjunctivitis. Sometimes the eyes alone are affected, other parts of the body being entirely free from rheumatic pains. In cases of this kind I have frequently doubted the existence of the affection, when properly directed treatment applicable to rheumatism would mitigate the disease.

The pain and swelling of the ocular muscles are usually confined to the sheaths of their tendons, to which the disease has extended, but particularly to the points of their attachments to the sclerotica, where there is frequently much infiltration, from which the conjunctiva is uplifted, and by reason of this pressure which it (the infiltration) exerts from beneath, the conjunctival vessels are emptied, giving this point the appearance of a pinguecula or an abscess. When there has been very severe inflammatory action I have seen this condition existing at the points of attachment of all the recti muscles. For a considerable time after such severe attack upon the ocular muscles the eyes cannot be moved in any direction without pain. The same causes that predispose to acute rheumatism of the other parts of the body will develop it in the ocular muscles, such as exposure to dampness and cold, and occupying damp rooms.

I am now abundantly satisfied that many of the intractable head pains from which so many suffer are due to some form of rheumatism of the ocular muscles, and that a due regard to this fact would contribute very greatly to palliating much suffering.

BACILLI ON A BALD HEAD.—Dr. Saymonne claims to have isolated a bacillus, called by him "bacillus crinivorax," which is the cause of alopecia. It is, he says, found only on the scalp of man, other hirsute parts of the body and also the fur of animals being free from it. The bacilli invade the hair-follicles and make the hair very brittle so that they break off to the skin. Then the roots themselves are attacked. If the microbes can be destroyed early in the disease, the vitality of the hairs may be preserved, but after the follicles are invaded and all their structures injured the baldness is incurable. The following is Dr. Saymonne's remedy to prevent baldness: Ten parts crude cod-liver oil, ten parts of the expressed juice of onions, and five parts of mucilage or the yolk of an egg, are thoroughly shaken together and the mixture applied to the scalp, and well rubbed in, once a week. This, he asserts, will certainly bring back the hair if the roots are not already destroyed, but the application of the remedy must be very distressing to the patient's friends and neighbors.

## GANGRENE FOLLOWING CONTINUED FEVER.[1]

By F. W. P. BUTLER, M.D.,

EDGEFIELD, S. C.

On the morning of November 27, 1888, I was called some miles into the country to see M. M——, twenty-eight years of age. Family history, as far as I could ascertain, was good, with probably two exceptions—his grandmother and an uncle, I learned, had died with a trouble very much like the one from which he was now suffering. On entering the cabin I found my patient lying over in a dark corner; he was very much emaciated, weak, and covered over with four or five heavy quilts. As soon as I entered the hut I recognized the characteristic gangrenous odor. I uncovered the affected limb, and discovered a cold, darkened leg, insensible to the touch of my hands, or to the prick of a pin. The line of demarcation had just begun to be formed, and I should have amputated then, but was compelled to endeavor to revive the dying leg. The family told me he had been sick two or three weeks, and had been attended by a physician in the neighborhood, who had given up the case.

I was certain I had a case of gangrene, with no lesion or traumatism to cause it. I really did not know the true cause then, but told them it was gangrene, and I would endeavor to save it, but thought it was too late. I dressed the leg antiseptically and with warm applications, and put the patient on tonic pills of iron, quinine, and strychnia, for then he was suffering no bowel or stomach trouble, but was intensely weak and reduced; also ordered small quantities of milk-punch regularly and often. I did my utmost to save the limb, but told them, after the second visit, that on my next visit the leg would have to come off, for now the line of demarcation had fully formed and the odor was terrific, and I saw that, under the existing circumstances, pyæmia would soon set in. So, on December 4, 1888, accompanied by Drs. Hill and Tompkins, I repaired to the place to amputate. I forgot to mention that when I first saw the man I also found him suffering from an immense, putrid, black, nasty smelling bed-sore in the lower part of the back, near the prominent portion of sacrum; this was protected as well as circumstances would permit. I amputated about six inches below the thigh-joint, as I was fearful of a recurrence of the gangrene. I made part skin and part muscular flaps. The parts were brought together with wire, and a wet sublimated dressing (1 to 2,000) applied over the stump, and on top of the wet dressing carbolized gauze and borated cotton, with bandages over all. The patient stood the operation well, notwithstanding his great weakness and depletion. I remained in the neighborhood that night, and he passed a tolerably good night. The whiskey and milk were increased, as was the quinine. The bed-sore mentioned above was dusted over with iodoform and wheat-flour, and protected from the bed. The enormous bed-sore added to the magnitude and apparent hopelessness of this terrible case. The patient was delirious, wandering, and feverish for four or five days, pulse weak, quick, and thready. I then put him on tincture of digitalis combined with the whiskey. Everything went on as well as I could expect until the fifth day, when, owing to a rise in the temperature and an unpleasant odor of the stump, I dressed it. Much to my regret, I found the femur had projected, then the flaps and the parts were in a complete state of suppuration. Evidently the man, in his delirium and restlessness, rolled over on the stump, and the bone pushed through the skin. I now determined to apply a dry dressing of sublimated gauze, and did so. In the meantime I did all I could to protect the bed-sore, but found a hard job, for two more bed-sores of a gangrenous character now appeared on each hip-bone, to which I also applied iodoform, and protected them with pillows as best we could. These bed-sores gradually sloughed off and began to granulate. I gave him as a nourishment bovinine and milk, with soup and light diet. Fortunately for me and my patient, his stomach never failed him once, and he took everything apparently with relish. He was doing well, the bed-sores healing, and the projecting bone gradually disappearing by healthy granulating tissue. After the febrile state had subsided to some extent, I prescribed sulphate of strychnine, gr. j., and solution of malate of iron, ℥ j., fifteen drops to be given three times a day. The quinine, gr. iij., was kept up continually.

I was just beginning to congratulate myself, as I now thought my patient was good to recover; but lo and behold, on the third week after the first amputation the other foot began to pain and get cold. I at once began warm applications, and tried every conceivable plan to save this leg, but all my efforts were futile. So soon as the line of separation began to form, I determined to operate, and, in fact, the poor unfortunate negro begged me to do so. I saw that the dorsal artery was affected, and that gangrene had begun. On February 7th, with the assistance of Drs. Beall and Nicholson, I amputated just below the knee, obtaining a good muscular flap. I concluded to dress this stump differently from the other, so I brought the flaps together with horse-hair and applied a dry dressing of sublimated gauze made of cheese-cloth. The man stood the operation well, took the same kind of anæsthetic as given before, easily. The bed-sores were healing, and the patient from this on gained strength daily. The stump healed by first intention, and there have been no signs of a return of gangrene in any part of the body. He is now doing well without his legs. I am led to conclude, from my experience with this case, though it is limited, and hardly enough to form opinions on, first, that as soon as we notice no signs of return of life to the part affected, sometimes even before the line of separation or demarcation forms, amputate high up above the seat of trouble; second, that judging from my meagre experience and that of my professional brethren in this town, a dry dressing antiseptic gives the best results.

[1] From a paper read before the annual meeting of the South Carolina Medical Association, 1889.

## POISONING BY TANSY.

Dr. W. A. Belt, of Kenton, O., reports the following case: "Mrs. K——, not having her menses for some five weeks, thought herself pregnant, and not wishing to have any more children followed a neighbor's advice and set about taking five drops of the oil of tansy every few hours. Not succeeding in bringing about her menses she took about one drachm on sitting down to breakfast. She felt no unusual symptoms for about a half-hour, when a "dizzy sensation" came over her. She ran out doors and a moment later was picked up by her husband in convulsions resembling epilepsy. There were the spasmodic contractions of the limbs, frothing at the mouth, and unconsciousness. I found her in this state, with a thready pulse, very intermittent, respiration scarcely perceptible, and cyanotic. Thinking there was enough food in the stomach from her breakfast to hold a good part of the oil yet unabsorbed, I administered apomorphia muriate, gr. $\frac{1}{10}$, hypodermically. In a few moments she vomited very profusely, there being a great amount of gastric juice. After this she revived by repeated doses of brandy, but did not regain her consciousness for two or three hours. She remembered nothing about what had happened. Her tongue was lacerated, as is often seen after a severe epileptic fit, the pulse ran up to 120, and temperature to 101° F. for the balance of the day. Headache persisted for three days, and fainting every three or four hours for two days. The menses made their appearance, but not from the action of the drug, for she was nursing a child about six months of age, and they had been irregular. There were no signs of an abortion." J

## Progress of Medical Science.

Regulation of Breathing in Seasickness.—Dr. Ivan A. Mitropolsky, of Moscow, warmly recommends, on the ground of his personal experience, the following simple method for preventing or aborting all symptoms of seasickness. As soon as giddiness, nausea, etc., appear, the author shuts his eyes, and begins to make deep and slow inspirations and expirations. In a few moments (sometimes after three or four respiratory cycles) the symptoms disappear, to yield to a comfortable subjective sensation. On their reappearance the same procedure is repeated again and again. If the recurrence be rather frequent, it is better to perform the procedure in a recumbent posture (with closed eyes). Since the time the author has begun to practise the method he never yet suffered from vomiting when on board. In referring to this case in the London *Medical Recorder*, Dr. Idelson says that Dr. Mitropolsky seems to think that the means proposed by him is novel. Meanwhile, in the *British Medical Journal*, March 24, 1888, p. 676, he will find a very interesting note by Dr. J. J. Leiser, in which the writer says (1) that seasickness is caused by irregular and imperfect respiration, leading, necessarily, to an inadequate aëration of the patient's blood, which consequently becomes poisonous to his brain and gives rise to sympathetic sickness; (2) that a system of regular, free breathing prevents sickness or rapidly relieves it; and (3) that his experiments were successfully repeated by Drs. G. C. Stockman and C. W. C. Prentice, who, having selected ten suffering passengers, each seated himself with five of them and "timed the breathing in the following manner: they (the doctors) raised the hand from the knee, indicating an inspiration, and down again for an expiration, thus timing the respirations to exactly twenty per minute. At the expiration of one hour the active symptoms in each case had entirely subsided." By this time the doctors had thoroughly educated their patients in the *modus operandi* of the cure. The cases continued to be permanent "cures" during the remainder of the voyage from Queenstown to the United States. The writers conclude by asserting that "the cure is infallible in all cases that persist in carrying it out."

Movable Heart.—Of five cases of movable heart studied by Professor Rumpf, three were the results of dietetic and medicinal attempts to cure obesity, one occurred after violent nervous excitement, and in one no cause could be assigned (*The Lancet*). The chief complaint of the patients was great debility and incapacity for work; other symptoms were pains in the chest, uneasiness, anxiety of mind, vertigo, asthma, and accelerated pulse. One symptom especially is always present in these cases—all the signs become less in the patient when lying on his back, and worse when he is on his side, and he feels better when he is standing up, though the pain does not disappear; occasionally, however, there is vertigo and malaise. The examination of the heart in the erect or horizontal position, and with the thorax bent forward, shows nothing whatever abnormal; when, however, the patient lies first on the left and then on the right side, the abnormal mobility of the heart becomes very distinct. In one case the apex beat shifted thirteen centimetres, in another from four to five centimetres. When the patient lies on his left side the area of the cardiac dulness seems larger, when on his right smaller, while at the same time the position of the aorta and of the pulmonary artery is also changed; in one case they moved one centimetre in the direction of the displaced heart. Dr. Rumpf considers the movable heart to be not a mere irregularity, but a pathological symptom, as the average normal movement of the heart is at most two centimetres to the left and one and a half centimetre to the right, as he observed this dislocation in one case of tuberculosis of the lungs and in one case of muscular atrophy.

Local Application of Chloroform in Epididymitis.—Dr. Clemens, of Frankfort, claims that he has obtained great benefit in cases of epididymitis, both specific and non-specific, by means of chloroform locally applied. He regards as most unsatisfactory the treatment of the affection by other methods as compared with his own, which he has employed now for a great many years (*The Lancet*). It consists in laying some cotton wool saturated with chloroform and spirit at the bottom of a large glass vessel, into which the genitals are then put and packed round with dry cotton wool, the buttocks and thighs forming a cover, this application being continued for from fifteen to twenty-five minutes, and repeated two or three times a day. Pathologically, he considers venous congestion of the epididymitis and the cord through retention of semen a predisposing cause of the disease. He also considers epididymitis as very likely to occur when gonorrhœa has been contracted in excessive venery. He mentions a case of treatment by chloroform, thirty-six years ago, not of epididymitis, but of periodical "heat," occurring in the human subject. The man used to suffer periodically from a form of orchitis, during which the testes felt hot and swollen, and the plexus pampiniformis was full and turgescent like a varicocele. He was ordered the local application of chloroform three times a day, from fifteen to twenty-five minutes each time, but the first time he bore the chloroform for nearly thirty-five minutes, after which the pain of the severe attack completely ceased and the swelling considerably decreased. This treatment lasted three days, during which time he was able to walk about, the cotton wool which had been used for the chloroform being put into the suspensory bandage and the testes covered with it. After that both the swelling and sensibility disappeared. Another case is mentioned where epididymitis had been caused by the continuous pressure of a rudder handle on the hypogastrium, in which similar treatment proved entirely successful. Again, a class of cases that is usually very difficult to treat—viz., that of gonorrhœal orchitis—seems to have proved fairly tractable when managed with the help of chloroform. Here one of the first signs of improvement was frequently the re-establishment of an old discharge, which was soon cured simultaneously with the epididymitis.

The Typhoid Bacillus in the Fœtus.—Dr. Eberth has reason to believe that the bacilli of typhoid pass from the mother to the fœtus. From a woman who died in the fifth month of gestation he removed the fœtus, and examined fluid from the heart, spleen, and lungs (*The Medical Press*). He found bacilli that possessed all the morphological and vital characteristics of the bacillus of typhoid. Dr. Gaffky, the well-known authority on the bacillus in question, agreed with the writer that the bacillus thus met and that of typhoid were identical. It is rather important to know whether the bacillus of typhoid can pass from the blood of the mother to the fœtus, *i.e.*, whether a child can have typhoid before its birth, and it appears on present evidence that it can.

Dysmenorrhœal Membrane.—Is membranous dysmenorrhœa a little more than menstruation and less than pregnancy? Can dysmenorrhœal membrane always be distinguished from the decidua in early pregnancy? These questions are of high import and deserve the attention of practitioners and histologists. The subject was raised at the July meeting of the Obstetrical Society of London, where some decidua-like fragments were exhibited. They had been discharged from the uterus some time after removal of the appendages. The theory that membranous dysmenorrhœa represents periodical abortion within one month after impregnation is very plausible. It is supported by Dr. Cory's case, published in the "Transactions of the Obstetrical Society," vol. xx., 1878, where no membranes were passed at period whenever the patient lived apart from her husband. The phenomenon might, on the other hand, be explained by the sexual rest which temporarily cured a true "dysmenorrhœa," as dis-

tinguished from an incipient pregnancy. All cases of membranes passed from the uterus at regular intervals deserve the most careful clinical record, and, at the same time, the membranes ought to be preserved in spirit and sent to a competent histologist. The habits of the patient should be investigated; the effects of separation from her husband very closely watched. On the other hand, the histologist, as a man of science, should feel sure that he can correctly interpret the microscopical appearances of the membranes. Above all, he must not give an opinion unless he knows, from practical research, the appearance of the endometrium at and between the catamenia, and also in early pregnancy.—*The British Medical Journal.*

Unsuspected Lead-poisoning.—Dr. Lermuseau has brought before the Liège Medical Society some instances showing that a good many cases of colic, the origin of which is unsuspected, are in reality nothing but cases of lead-poisoning. A large number of them are due to the practice of pumping up beer in public-houses through leaden pipes, or at least through pipes which contain a considerable proportion of lead. Publicans and others frequently drink this beer early in the morning on an emptv stomach, and this habit is a most fruitful source of lead colic. Of course, in many cases there is a blue line to be found on the gums, but sometimes this is absent, and then the diagnosis is very difficult. Occasionally, the so-called method of Cicconardi may be useful in clearing up the diagnosis. It has been employed in Professor Rommelaere's wards, and consists in painting the surface of the skin covering the thorax with a six per cent. solution of sulphite of soda. If lead is present in the tissues a dark discoloration caused by the formation of the sulphide soon makes its appearance. Dr. Lermuseau complains of the apathy and incredulity of publicans even after their attention has been called to the danger of using leaden pipes for their beer—a danger from which the publican is usually the very first to suffer. It is urged that a stringent law ought to be passed entirely forbidding the use of leaden pipes for beer-pumps. Dr. Lermuseau suggests the substitution of glass or hard rubber pipes, but these substances are less convenient, because they cannot be bent in all directions in the way that lead can. It would appear that, according to a law made in 1790, the communal administrations have all along had ample power to deal with cases of this kind, if they would only exercise it. Something more stringent is evidently necessary, and Dr. Lermuseau urges upon his *confrères* to bring all the pressure possible to bear upon members of the two Houses of Parliament, in order to get some more satisfactory legislation on the subject.—*The Lancet.*

Physical and Mental Changes after Removal of Ovaries or Uterus.—Dr. Glævecke, of Kiel, has lately published a paper in the *Archiv für Gynækologie* on this subject. According to this author the changes usually met with were those observed at the menopause (*Berlin Cor. Medical Press*). Menstruation permanently ceased, immediately or shortly after the operation of removal, in eighty-eight per cent. of the cases. In the remainder it was less frequent and more scanty. Practically, no vicarious menstruation was observed. Menstrual molimina were observed in thirty per cent. In the time between the periods the familiar characteristic disturbances were observed—hot flushes, perspiration, and faintness. He looks upon them as disturbances of the vaso-motor system, in consequence of the cessation of the ovarian function; an observation, by the bye, that does not throw much light on the subject. He does not remark the very long continuance of this most uncomfortable condition in many of the cases—four and five years. In four cases out of a total of forty-three, palpitation and headache came on, in one nausea coming on several times a day, in another vomiting, in one diarrhœa, in one acne of the face lasting over a year, and in two increasing weakness of intellect. Atrophy of the internal genitals was a consequence of the operation. In twenty-three cases in which the operation was performed for myoma uteri, distinct shrinking took place in the tumors in ninety per cent. In forty-two per cent. of the cases a distinct increase in weight, due to deposit of fat, was observed. Sexual desire was unchanged after removal of ovaries in only a few women. Both desire and pleasure were much diminished, but not in the same proportions in all cases. As regarded the psychical condition, almost always a depressed, low-spirited condition was remarked. Many women became melancholic, others showed a changeable and petulant disposition. Actual psychoses developed in three cases; two recovered in the course of a year, the third was incurable.

The changes were different when the uterus was extirpated. Menstruation ceased and no vicarious menstruation followed. Out of thirteen cases of total extirpation of the uterus, strong molimina were observed in nine. If the ovaries were not removed atrophy of the external genitals did not take place. But little increase of weight took place after extirpation of the uterus. Sexual matters were almost unchanged, a slight diminution of sexual pleasure was acknowledged in a few cases. Psychically, no change was observed in one-half of the cases; in more than a third a melancholy so great as to constitute a psychosis was observed. On the whole, the bodily and mental changes after castration were much greater than after extirpation of the uterus.

Acute Traumatic Pneumonia.—Dr. Sokolowski has published a paper on acute croupous pneumonia of traumatic origin. Two cases came under his observation lately. They refer to lads of fourteen and nineteen, who received violent traumatic injury to the chest anteriorly, and in whom, several days later, there developed croupous pneumonia localized in the region injured. In both, the attack was rather severe and characterized by an intense local pain, the course of the disease being typical, and terminating by a well-pronounced crisis. Such cases are well known to clinicians. They are not so very rare, to judge from the fact that among Frerich's 300 cases there were as many as 14 which had a distinct etiological connection with traumatic causes. From the point of view of modern etiological theories their causation may be explained, seemingly, pretty simply: a traumatically injured pulmonary tissue appears to lose its power or resistance to the pathogenic microbe of pneumonia; hence the inflammation arises. Practically, cases of the sort are especially important in forensic respects. The expert may be asked whether this or that traumatic injury to the chest (for instance, inflicted during a fight) can be regarded as a real cause of an attack of pneumonia developing more or less immediately after the injury. Such cases as Dr. Sokolowski's seem to justify a positive answer to the question.—*St. Louis Medical and Surgical Journal.*

The Infective Period in Contagious Diseases.—In the *Glasgow Medical Journal*, Dr. James Finlayson contributes an article in which he has collected and tabulated the views of recent authorities on the infective and incubation period in contagious diseases. The author has drawn up three tables, one showing the various views of well-known authors as to the infective period, another showing the period of incubation, and a third showing the period of quarantine necessary to enforce in cases where the patient has been exposed to infection, before they should be allowed to be considered safe to mix with others. Some such rules are also required as to the time when it is safe to allow healthy children to return to school, if they have brothers or sisters suffering at home from infectious diseases, especially if they themselves have once had the disease. The infective period for scarlet fever is from seven to eight weeks; measles, three to four weeks; Rötheln rather less; mumps varies from two to four weeks, and whooping-cough is usually put down to eight weeks or more. The paper is a very instructive one, and every general practitioner would do well to keep a copy of it always ready for reference.

# THE MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PROPRIETORS AND PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

**New York, September 28, 1889.**

## AN OLD SURGICAL SUPERSTITION EXPLODED.

DR. H. A. HARE has been making an experimental study of the effects of the entrance of air into the circulation, and he has obtained results quite opposed to current surgical teaching regarding this matter.

Dr. Hare experimented upon seventy dogs, of all sizes, ages, and conditions. He injected air into the jugular veins and carotids in doses of from a slight bubble up to forty cubic centimetres. He found that air injected in the above amounts into the veins caused no serious effects whatever, except, perhaps, a brief quickening of respiration and fall of blood-pressure.

When air was injected into the carotid, however, the effect was different. In from one-half to one second respiration ceases at once, unconsciousness asserts itself, and the animal is apparently dead, save for the action of the heart, which keeps on as if nothing had occurred. In a moment respirations are renewed, the breathing becomes at first more powerful, then less and less so till death really ensues—a result which can be indefinitely postponed provided artificial respiration is kept up. Sometimes the animal begins to breathe voluntarily, and lives independently of any such aid; in others he dies at once when the artificial respiration ceases.

Dr. Hare reviews all the various experimental and surgical evidence on which is based the prevalent opinion that air getting into the veins causes death. He thinks this evidence quite valueless and adds: "While we have a large number of cases reported of sudden death under operations where veins were opened, in the majority of them the cause of death has been guessed at and not proved. The only case which approaches in any way toward authenticity is that of Mott, who saw a serious but not fatal result induced by the entrance of air into the facial vein, and even this is not a proved case. The case of Barlow is equally doubtful as to the real cause of death.

"There are a number of cases on record where death has resulted, according to the physician in charge, from the entrance of air into the uterine sinuses." These are not discussed by the writer, as they are somewhat different in their character, in that the character of the accidents and the peculiar anatomical arrangement of these veins render the entrance of large amounts of air more easy of accomplishment.

The conclusions reached, then, are: 1. Death never occurs from the entrance of air into the ordinary veins of the body unless the quantity be enormous—from one to several pints, a quantity which cannot enter unless deliberately sent in by the surgeon.

2. The cases on record have been due to other causes than air and have not been proved.

3. The tendency of the vessel to collapse and the leakage of blood prevent any entrance of air, and it would seem probable that a clot has generally caused death, not the air itself.

It must still be remembered that Dr. Hare's positive evidence of the innocuousness of air in the veins is based entirely on experiments upon lower animals.

## THE NEW BUILDING FOR THE ACADEMY OF MEDICINE.

THE corner-stone of the new building for the New York Academy of Medicine will be laid, with appropriate ceremonies, at Nos. 17, 19, and 21 West Forty-third Street, on Wednesday, October 2d, at 4 P.M. Thus the time comes for a realization of hopes, long deferred, for a fitter dwelling-place of the medical profession of this great metropolis. It will be the new home around which will eventually centre all those social and scientific influences, which will make the medical fraternity a power for good, not only in this city but throughout the land. It will, we trust, be an event ever to be remembered in the medical history of New York as marking an era when the foundations for professional unity and brotherly love shall be securely laid, and when each and all shall be stimulated by the laudable ambition to work for the common good. It well becomes one and all to enter heartily into the spirit of the occasion. Every member of the Academy should lend the influence of his presence, and prove to the laity that their generous donations have not been vainly or unworthily bestowed.

Heretofore the profession has not been as responsive to public interest as it should have been. The laymen are hardly prepared for such indifference, and are consequently ready with excuses when donations are required. It goes without the saying that the profession must first show itself in earnest in enterprises of the kind to which we refer, in order to have a becomingly responsive action from the men of money and influence who can aid us. Therefore a large gathering is to be expected—members of the Academy surely, and as many of their friends, male and female, as can come. The exercises will be interesting, and the addresses, particularly the one on behalf of the Academy, will be well worth hearing. The following will be the programme:

Invocation, by the Right Rev. Henry C. Potter, D.D.; Address by Ex-President A. Jacobi, M.D.; Remarks by the Hon. Grover Cleveland; Laying of the Corner-stone by the President, Alfred L. Loomis, M.D. Benediction.

## SUCCESS IN PRACTICE.

SIR ANDREW CLARK, one the most successful and distinguished of English physicians, has recently had a portrait of himself presented by the staff of the London Hospital. In his speech replying to the presentation address Sir Andrew gave some account of his life and of the causes of his professional success. His story deserves perusal. Sir Andrew was born in Scotland, and went to

London thirty-six years ago, a young man in delicate health and without a single friend or influential connection. He had, however, a "small patrimony" and was enabled to pursue the study of pathology and to keep himself quite free from any intrigues or quarrels. He devoted himself to work, and before many years, despite ill-health and opposition, he was made physician to London Hospital. His subsequent success was slow but continuous, and was achieved without any definite expectation at first that it would eventually be so brilliant. Sir Andrew gave the following as some of the conditions necessary for success in medicine:

"Firstly," he said, "I believe that every man's success is within himself, and must come out of himself. No true, abiding, and just success can come to any man in any other way. Secondly, a man must be seriously in earnest. He must act with singleness of heart and purpose; he must do with all his might and with all his concentration of thought the one thing at the one time which he is called upon to do. And if some of my young friends should say here, 'I cannot do that—I cannot love work,' then I answer that there is a certain remedy, and it is work. Work in spite of yourself, and make the habit of work, and when the habit of work is formed it will be transfigured into the love of work; and at last you will not only abhor idleness but you will have no happiness out of the work which then you are constrained from love to do. Thirdly, the man must be charitable, not censorious—self-effacing, not self-seeking; and he must try at once to think and to do the best for his rivals and antagonists that can be done. Fourthly, the man must believe that labor is life, that successful labor is life and gladness, and that successful labor, with high aims and just objects, will bring to him the fullest, truest, and happiest life that can be lived upon the earth."

---

## THE BRITISH MEDICAL ASSOCIATION DIVIDED.

The British Medical Association has been of late years so continuously prosperous, and so active in every kind of work pertaining to the interests of the medical profession, that the announcement of a fatal split in its ranks awakens astonishment as well as regret. Yet, if we may believe the *Medical Press and Circular*, "L'affaire Mackenzie has assumed proportions which threaten the life of the Association." Our contemporary goes on to say that "The party of dissatisfaction has publicly intimated that unless the Council listens to the representations which it has made as to the management of the *Journal*, it will secede from the organization. The Council has not had the discretion to recognize that this party includes the majority of the very best men in the Association, and has been so undiplomatic as to return a gratuitously curt and offensive answer to their letter; there is every reason to apprehend that the threat of the dissentients will be carried into effect without delay, and that the defection will take with it out of the ranks of the Association most of those members whose presence has lent *éclat* to the meetings.

"The influence of the party in hostility to the Council cannot fail to be vitally injurious to the Association, and already has had the effect of preventing the annual meeting from taking place next year in London, as was intended."

We incline to think that our esteemed contemporary takes rather too dark a view of the matter. The extraordinary growth and popularity of the *British Medical Journal* has never been a source of unmixed satisfaction to its rival weeklies, and a split in the Association might mean, perhaps, a little more even distribution of circulation. If, however, the medical profession of England allows its strongest and most useful organization to be wrecked simply because of personal dissatisfaction with one of its members, it will be a lasting disgrace to our profession. And it will afford the strongest proof yet offered that doctors cannot agree, even in trying to promote their own interests. Indirectly it would also affect our own Association, which can yet but ill afford discouragements.

---

## NÆVUS TREATED BY INJECTION OF ALCOHOL.

The treatment of nævus is various, and, if the old rule holds good, this fact proves that no method of treatment yet invented is satisfactory in all cases. Dr. Holgate, (*Archives of Pædiatrics*, June, 1889), describes still another method, as far as he knows a new one, which has given satisfaction in the two cases in which it was tried. He first reviews briefly the best methods heretofore employed. The compound tincture of iodine is efficacious when applied to small nævi, but fails to cure large ones. Tartar emetic, one part by weight to four of galbanum plaster, collodion, collodion with corrosive sublimate, and creosote, have all proved satisfactory in some cases. Vaccination on the nævus cures at times, as does also the application of caustic potash or of nitric acid, but all of these leave a scar which may be more unsightly than the nævus itself. Injection of perchloride of iron has been successful; but in a case cited ten minims produced instant death in a child. Setons have wrought cures sometimes, and cure has also followed ligation, after the passing of pins under the tumor. Excision is too bloody, and leaves a scar. The passing of a silver wire into the skin around the nævus, and out again at the point of entrance, the wire being then gradually tightened, has cured without leaving a scar. Many other methods have been employed, one of the best being destruction of the growth by electrolysis. The objection to this method is that it requires the use of an electric battery and needs considerable practice. One of the latest suggestions is to apply the ethylate of sodium or potassium to the nævus. If the application is repeated from time to time it will eventually effect a cure.

In 1885 Dr. Holgate was requested to remove a pendulous vascular nævus, situated outside the right ala nasi of a boy four years of age. It was half the size of a filbert, soft and compressible, but swelling out quickly when pressure was relaxed. At birth it was a port-wine mark, level with the skin. It had several times bled profusely and persistently. Fearing hemorrhage and a resulting scar, if scarification were used, he determined to try the injection of ninety-five per cent. alcohol. Applying a common eyelid-clamp around the base of the growth, to arrest the circulation, he passed a hypodermic needle through its centre, longitudinally, near its base, and injected

from five to seven minims of rectified spirit of wine, gradually withdrawing the needle as he injected. The tumor became quite solid. Finding it, a fortnight later, softer and much shrunken, he now passed the needle into the growth at a point from which its vessel-supply started. Six weeks later it was one-eighth its original size. It was injected again at this time, and a fourth time two months later. As the nævus had become so small, it was quite difficult on these last two occasions to pass the needle into the skin. Three years later, when this article was read, the nævus had become so reduced and the skin over it had returned so far toward its normal condition that an observer would see no difference in the alæ unless his attention were directed to the existence of the nævi. No treatment was now employed except painting the spot from time to time with glycerine. There was no scar, except at the point where it had previously ruptured spontaneously and bled.

The second patient, a baby, two months old, presented a nævus on the chest, which was at birth only a port-wine mark, but had rapidly grown into a vascular nævus nearly as large as that before described. The growth was encircled by a metal ring, and circulation to and from the part arrested. Alcohol was injected, as in the former case. But one injection was made, and this not only arrested growth, but caused its disappearance as a tumor. A month later it was level with the skin, and three-fifths of its surface had regained the normal color of the skin. There was no scar. The part which remained of a port-wine color spread a little during the next three months, but another injection or slight scarification would probably remove all the remnants of the nævus.

Encircling the growth by a ring is always to be recommended, as it confines the alcohol to the diseased part, and also makes it act more strongly. By contracting the vessels beyond the nævus, it prevents the entrance of clots into the circulation.

The syringe must, of course, be free from air when the injection is made. This method has the advantage of simplicity, and the necessary apparatus is already at hand. Dr. Holgate thinks that with ordinary care it is safe. He suggests its use in goitre.

---

## SYPHILIS IN OLD AGE.

THERE are few subjects in medicine that can compare with syphilis in the richness and variety of its literature, yet singularly enough, the peculiarities of the disease in the aged seem to have passed comparatively unnoticed by syphilographers. The first monograph on the subject dates back only to 1878, when Sigmund, of Vienna, published the results of his study in this field; and since that time not more than three or four memoirs, as far as we know, have appeared. This must be due rather to the paucity of clinical material than to inattention on the part of students of syphilis, for the disease, when contracted in old age, while not remarkably different in its course from that of the same affection in younger subjects, yet presents certain modifications which are sufficiently striking to deserve study.

The latest contribution to the subject of senile syphilis is presented by Dr. Alexandre Renault, in the *Annales de Dermatologie et de Syphilographie* for March, April, and May, 1889. In this article the author presents a fairly exhaustive review of the subject, and points out quite clearly the modifications imposed upon the course and symptoms of the disease by the senile changes in the organism. As might be expected, since the system is already weakened by the advance of age, and is, therefore, less able to combat disease, syphilis is a much more serious matter in the declining years of life than it is in early manhood.

The differences are apparent even in the course and duration of the primary sore. The chancre has at first much the same appearance as that in persons of any age, but it has a remarkable tendency to ulceration. This is a point of some importance, since it is liable to lead to an error in diagnosis, especially if the chancre be extra-genital, for it may in such case readily be confounded with epithelioma, which is so common in old age. Cicatrization is also slow, many months sometimes elapsing before this process is complete. Another point worthy of notice is the tardiness in the appearance of adenitis. In the adult this makes its appearance usually within a fortnight, while in the aged its development is often a matter of six or seven weeks.

But it is during the secondary period that the peculiarities of senile syphilis are the most striking. The syphilitic fever is apt to be quite marked; indeed, the condition of the patient at this time is sometimes so grave as to give occasion to the diagnosis of typhoid fever, or of profound malarial infection. The syphilides of the secondary period are distinguished by their tendency to become confluent, by their obstinacy and resistance to ordinary therapeutic measures, by the frequency of relapses, and finally, by a remarkable proneness to assume the characteristics of tertiary eruptions. Cutaneous gummata are not uncommonly observed at this stage, and in general they appear much earlier in the aged than in adults. On the part of the nervous system the disturbances are often most marked. Disorders of sensation and motion, of the special senses of sight and hearing, and of the mental functions are commonly met with at this period. And, finally, a profound anæmia and a most pronounced cachexia are often seen, and indeed may be regarded as characteristic of the secondary stage of senile syphilis.

It is often difficult to separate the tertiary from the secondary lesions of syphilis in the aged, since there may be no interval of apparent cure between them, the tertiary accidents supervening directly upon those of the second stage. The cutaneous lesions of this period are characterized by their more general diffusion over the body, by a marked propensity to ulcerate, by persistence despite active treatment, and by a pronounced tendency to relapse after apparent cure. The nervous symptoms are similar in character to those seen in adult subjects, but they are more grave as a rule, and appear much earlier.

We have passed over many points of great interest, which are dwelt upon by Dr. Renault, owing to the necessity of being brief in our review. But we have drawn from him sufficiently to show that syphilis in the aged is an affair of much greater moment than it is ordinarily in adult life. It seems, indeed, as though nature knew that the subject of her displeasure had but a short time in which to pay the penalty of a violation of her laws, and that she was therefore impatient to crowd all the stages close together, so that her chastisement, though more brief, should be proportionately more severe.

# News of the Week.

Ex-Surgeon-General Joseph Beale, with relative rank of Commodore, United States Navy, died on September 23d, at his residence in Philadelphia, Pa. Dr. Beale was born in that city, December 30, 1814, and received his classical and medical education in the University of Pennsylvania, from which institution he graduated in 1836. He practised his profession for one year, at the end of which period he entered the United States Navy as Assistant Surgeon, and afterward rose to the position of Surgeon-General of the Navy, to which he was appointed in December, 1873. He was placed on the retired list in 1876.

Dr. Chrobak, of Vienna, has succeeded the late Professor Breisky in the Chair of Obstetrics and Gynecology at the University of Vienna.

The Cold-bath Treatment of Typhoid Fever in Australia.—Dr. Hare, of the Brisbane Hospital, at Sydney, states (*Medical Press*) that the cold-bath treatment of typhoid fever has been rigidly applied since July, 1887. The result has been a reduction of the mortality-rate from 14.8 to 7 per cent.

Doctors' Bills Unpaid.—A controversy has arisen between Health Commissioner Griffin, of Brooklyn, and the local Civil Service Commission over the action of the former in appointing twenty physicians to serve as sanitary inspectors during the summer months. They were selected by the Health Commissioner, and were to get $2.50 a day each. They put in their bills for eighteen days' work during July, and Commissioner Griffin approved them. They were forwarded to Auditor Rutan, who was about to audit them, when he received a letter from the Civil Service Commission ordering him to throw the bills out, as they were illegal. They were at once returned to Commissioner Griffin. The trouble lies in the fact that the appointments of the physicians should have been made legally from the eligible list of the Civil Service Commission. The Health Commissioner appointed whom he chose, and if the young doctors do not get their pay they may thank the commissioner.

Trying to Close a So-called Medical College.—Dr. L. D. Broughton, President of the New Jersey College of Medicine and Surgery, whose diplomas the Hudson County Board of Health refused to recognize a month ago, has made a complaint to the State Attorney-General, and asked for a mandamus compelling the Board of Health to issue certificates to the students who hold diplomas. The college is said to have received its charter in 1870 by a special act of the Legislature. It did not open a school until 1887, and the first students graduated from it this year. The counsel to the Board of Health says that the board must recognize the diplomas issued by the college, and it was against his advice that the board acted. Dr. Leonard J. Gordon, president of the board, says the fact that the college leans to eclecticism had nothing to do with the board's action. He says the board will fight any proceedings the college may bring to compel it to recognize the diplomas.

The Johns Hopkins Hospital: A Statement from President Gilman.—In view of the reports which have recently been published respecting the Johns Hopkins University, President Gilman authorizes the statement that the university will begin its next year on October 1st with unimpaired efficiency. Neither the salary of the president nor those of the professors have been cut down, and several new appointments have been made. The indications during the summer have pointed to the usual number of students, and the courses of instruction will be given as announced in the programme. As to the finances of the university, it is no secret that the income derived from the Baltimore & Ohio Railroad was cut off some time ago, but the accumulated income of former years, the income from investments outside of the railroad, the income from tuition (which amounted last year to nearly $40,000) are available. Besides all this, a number of generous persons have subscribed the sum of $108,000 to be expended as an emergency fund during the next three years. In addition, a new building, given by Mr. Eugene Levering, of Baltimore, is now going up. A lectureship in literature has been endowed by a gift of $20,000. By the death of John W. McCoy the university inherits at once his choice library of eight thousand volumes, and is the residuary legatee of his estate. The exact amount to be received from this source cannot yet be ascertained, but the most prudent estimates place it above $100,000, exclusive of the library. This gift is free from conditions. It is safe to say that within six months the Johns Hopkins University has received from these various sources nearly $300,000, and other gifts are expected. The national character of the institution is a strong reason why its work should receive important aid from a distance. It will thus be seen that no consideration need be given to alarming rumors, as the present efficiency of the university is assured for the next three years.

Dr. J. Emmet O'Brien, of Scranton, Pa.—The item in a recent issue of The Medical Record referring to an article on "Sensibility of Telegraphers" should have given the residence of the author, Dr. O'Brien, as Scranton, Pa., where he has long been one of its leading practitioners.

The Medical Department of the Paris Exposition.—In view of the prospect of a World's Fair being held in this country in 1892, the medical work of the Paris Exposition is of interest. Its report for the months of June and July, has been published. There is, it appears, a well-organized ambulance system. The stretchers are always ready to pick up patients, who are then attended to and conveyed to their own homes or to a hospital. The following statistics may be found interesting. The medical service had consumed during the two months of June and July 2 litres of ether, 20 litres of camphorated spirits, 60 litres of eau de mélisse (a kind of aromatic spirits), and 100 litres of carbolic water. Fifty mustard plasters were applied, and 300 hypodermic injections of morphia and of cocaine were practised on patients at the Exhibition. The number of dressings amounted to 1,780, of which 935 were for visitors. One workman died from accident; among the visitors there were six cases of sudden death. In this period of two months 18 workmen and 490 visitors were sent to the hospital.

# Society Reports.

## ASSOCIATION OF AMERICAN PHYSICIANS.

*Fourth Annual Meeting, held in the Army Medical Museum and Library, Washington, D. C., September 18, 19, and 20, 1889.*

FIRST DAY, WEDNESDAY, SEPTEMBER 18TH—MORNING SESSION.

THE Association was called to order at 10 A.M., by the President, DR. FRANCIS MINOT, of Boston.

The first business was the reading of the President's address.

### THE PROGRESS OF MEDICINE DURING THE LAST FIFTY YEARS.

The immediate causes of the great advancement of medicine were the growth of physiology and pathology, including bacteriology, and the improvements in clinical and laboratory teaching of the present day, which have led to a better acquaintance with the nature and causes of disease, to a more rational and successful therapeutics, and to the prevention by means of hygiene of a large number of diseases, including some of the most fatal. These means have been greatly aided by the progress of science in general, and by the conveniences of modern civilization, which enable observers from different countries to assemble together for interchange of knowledge and experience. A large share of medical progress is also due to the dissemination of knowledge by means of well-conducted journals, which enable thousands of practitioners who cannot leave their homes, to be constantly supplied with the most recent discoveries relating to pathology and the diagnosis and treatment of disease. The organization of this Association is particularly adapted for the progress of medical science, representing no one section of our country, but including practitioners from all parts of the United States and Canada, whose experience, knowledge, observation and ability are brought together for comparison and for mutual instruction.

The President reported the deaths of the following members: Drs. H. D. Schmidt, New Orleans; John C. Dalton, New York (honorary member); Robert Palmer Howard, Montreal; and Edward T. Bruen, Philadelphia.

DR. C. F. FOLSOM, of Boston, read a paper entitled

### THE EARLY STAGE OF GENERAL PARALYSIS.

The author first reported a number of cases illustrating the early stage of the disease, in which the motor disturbances were very slight, and might readily be overlooked and escape detection. The striking loss of muscular control or power, generally considered a part of the disease, was not found until a late period of the disease. The mental symptoms consist in impairment of a peculiar quality, often so slight as to be made out with difficulty.

The disease arises most commonly under prolonged strain, particularly when associated with unaccustomed excesses. At least two-thirds of the general paralytics have had syphilis. The relation of the disease with syphilis is too frequent to be accidental. The disease is, however, not a stage of syphilis, and is not benefited by specific treatment. The prognosis is probably not so hopeless as it is generally considered to be.

The common early treatment is harmful. Foreign travel is injurious. The only hope of at least partial cure or marked amelioration is in entire mental and physical rest.

#### DISCUSSION.

DR. ROBERT F. EDES, of Washington, reported the case of a man suffering now from pronounced general paralysis, in whom the first symptoms of the disease made their appearance some twenty years ago. If the anatomical view of general paralysis is accepted, he did not consider it strange that mental symptoms might precede the motor, depending upon the seat of the lesions.

DR. S. WEIR MITCHELL, of Philadelphia, was sure that certain cases of general paralysis began most markedly with motor trouble, while others began most decisively with mental conditions. In regard to syphilis, he agreed with the author, except that he had seen cases due to syphilitic disease in which cure followed specific treatment. He had also seen cure follow, in a small number of cases, where the treatment was begun in the early stages, but where the motor disturbance and the mental incapacity were sufficiently marked to render the diagnosis reasonably certain. In all of these cases there had been a total abandonment of all previous pursuits, with absolute mental and physical rest. He agreed with the author that foreign travel was often injurious.

DR. JAMES J. PUTNAM, of Boston, remarked that the fact that syphilis acts in this disease not by producing a direct lesion, but in an indirect manner, justifies us in looking for other causes of degeneration which might act in a similar manner. He asked if the reader had seen any cases in which chronic lead-poisoning was the apparent cause of the general paralysis, and related a case in which the imperfect and slow speech, the imperfect handwriting, and the expression of apathy and indifference, suggested a diagnosis of general paralysis. In this case there was, however, a history of drinking of water contaminated with lead, and there were certain local symptoms indicating lead-poisoning.

DR. WILLIAM PEPPER, of Philadelphia, believed that he saw these cases from a different stand-point than that of Dr. Folsom. They come to him as cases of dyspeptic lithæmic disturbance and the like, and are under his care for some time before symptoms leading to recognition are developed, sometimes for years before the paretic symptoms appear. He could not regard syphilis as in any way essential in the causation of general paralysis. In regard to the early stages of the disease, there was not one symptom mentioned by Dr. Folsom, or described by others as indicating the early stage, which he did not often find in cases of nervous lithæmia. There may be a grouping of these symptoms, or a delicacy on the part of the diagnostician, which will enable a finer and finer shade of these differences to be recognized, which does constitute a basis of diagnosis. He thought that general paralysis could be initiated by many disturbing, depressing, or irritating causes, and that in its early stages and slight degrees it was capable, not rarely, of being entirely cured. If these cases are permitted to go on with neglect of hygiene and with excesses, sexual, alcoholic, or business, a notable proportion will end with symptoms of general paralysis.

DR. C. F. FOLSOM, of Boston, said in regard to lead, that while he had seen cases in which this agent had produced symptoms similar to the initial symptoms of general paralysis, he had not seen a case in which the terminal symptoms of general paralysis had been produced. As illustrating apparent cure after specific treatment, he referred to a case in which the use of large doses of iodide of potassium apparently produced complete recovery, and the patient returned to his previous business. The symptoms after several months reappeared, and have continued to steadily progress. Whether this is the result in all such cases, he was unable to say.

DR. JAMES STEWART, of Montreal, read a paper entitled

### TETANY.

The details of the following case were referred to:

The patient, a male, aged forty, has been troubled during the past eight years with regularly recurring attacks of tetany. He served as a soldier during the American civil war. Suffered at that time and subsequently from chronic dysentery and malarial attacks. For upward of ten years he has been troubled with diarrhœa. Patient is tall, emaciated, and anæmic. The first subjective symptom of his tetany is usually double vision,

which is quickly followed by characteristic contractions of the flexor muscles of the hands. Occasionally, the flexors of the forearms and the adductors of the arms become spastic, muscles of the face almost constantly suffer, muscles of the lower extremities rarely. The affected muscles are the seat during the attacks of fibrillary twitching. The attacks often last several days (seven to twelve), unless terminated by the very free use of morphia.

The galvanic irritability of the nerves is found to be greatly increased, also the mechanical irritability of both nerve and muscle. Knee jerks exaggerated during attack, absent in intervals. Œdema of the hands and arms, with herpetic eruptions, frequently to be seen after particularly severe attacks. The quantity of urine excreted during attacks is usually normal in amount, and contains urea and indican in great excess. Patient has been under observation for more than three years, and it has been noticed, during the past two years, that he has been getting gradually dull and apathetic. It takes him a long time to answer questions, he complains of general numbness, his face and lips are swollen; symptoms closely resembling those seen in myxœdema.

Tetany may be divided into four varieties:

1. Epidemic or "rheumatic" tetany, common in Europe, but extremely rare in America. The course is acute and favorable.

2. Tetany from exhausting causes, as lactation, diarrhœa, etc. Course is chronic and favorable.

3. Tetany from removal of the thyroid glands. Course generally is usually either quickly fatal or chronic and incurable.

4. A form of tetany occurring in cases of dilatation of the stomach. Very fatal.

Infantile tetany is excluded from above division, as what is so frequently called tetany in infants is not that disease. No doubt, true tetany may occur in childhood.

*Experimental Tetany.*—When the thyroid gland is removed from cats, dogs, or monkeys, a condition very similar to the typical tetany of the human subject is observed, viz., fibrillary tremors and intermittent spasmodic contractions. Death usually follows in a week, and no change can be found to adequately account for it.

The fact that there is a great increase in the electric irritability of the nerves after the removal of the thyroid gland is strong evidence of the similarity of the tetany of man and animals. Of the many forms of muscular contractions seen in man, in none, with perhaps the exception of cholera, do we find any marked increase of the electric irritability of the nerves and muscles.

*Morbid Anatomy.*—No changes that in any way can be considered characteristic have been described.

*Nature of.*—All recent observers tend to confirm the conclusion of Schiff, that the tetany following removal of the thyroid gland is directly due to the loss of the gland, and that the thyroid gland in some way has a direct influence over the nutrition of the nervous system. It is difficult to explain how causes so diverse in their operation, as "rheumatic" influences, diarrhœa, pregnancy, lactation, and removal of the thyroid, can induce similar symptoms. It appears probable that impoverishment of the nerve-centres is one of the main factors in its production.

Dr. John T. Carpenter, of Pottsville, Pa., read a paper entitled

TETANY, AND A NEW THEORY OF ITS PATHOLOGY.

The author defined tetany as a nervous disorder accompanied by tetanic spasm of an intermittent character, which may extend from the extremities to the jaw, and be reproduced during its periods of intermission at will, by pressure on the track of the affected nerve-trunk, or over the blood-vessels obstructing the circulation.

A historical review of the disease was given. Tetany was regarded, not as a special disease, but as a sequel of precedent phenomena only. The affection was regarded as the result of septic absorption. The diminution of cases of tetany, coincident with the successful treatment and the prevention of septic poisoning, was regarded as an argument in favor of the connection between septicæmia and tetany. Cases illustrating this view were cited. The views previously held in regard to the pathology of tetany were discussed, and considered untenable.

DISCUSSION.

Dr. Francis P. Kinnicutt, of New York: I have seen but two cases of intermittent tetany, both occurring in patients with dilatation of the stomach. In one the dilatation was due to pyloric stricture, resulting from cancer; in the other there was non-malignant stricture. In both of these cases the conditions were favorable to absorption of poisonous matter.

Dr. F. T. Miles, of Baltimore, reported the case of a young woman, twenty-two years of age. She had suffered for six or eight years from dilatation of the stomach; had vomited acid matter, but never offensive; had several times had numbness of fingers and toes. She suffered her first attack of tetany twenty-four hours before her death. In this case the stomach had never been washed out.

Dr. A. Jacobi, of New York, had been struck with the stress laid by the readers upon sepsis as the cause of tetany. In one of the cases reported by Dr. Stuart, which he thought was due to absorption of putrid material, the stomach was twisted, and Dr. Jacobi suggested that the intermittent contracture was due to nervous influence, resulting from the twisting, rather than to absorption. He did not doubt that there were cases in which septic absorption produced such symptoms, but when we recall the fact that the contracture is temporary, we must conclude that the influences giving rise to that attack were also temporary. Many of these cases are, I think, the result of nervous irritation. In some of the cases reported, I should attribute the condition to anæmia.

Dr. James J. Putnam, of Boston, remarked that the reported cases of tetany showed such a variety of infectious sources, that it seemed hardly probable that they should act in such a similar manner, unless there was something else behind. Two or three things are to be considered: First, the influence of habit—the disease set up by a variety of causes may continue as a result of habit; second, the suggestion that in such cases of disordered action we have to deal with an over-sensitiveness of physiological arrangement is important. In these conditions we have the disordered manifestation of what is really a function, but one which is not ordinarily recognized, as it has no independent existence. It would seem that in the absence of further knowledge with regard to infection, and the manner in which this infection, arising from various sources, may act, we should insist upon the possibilities of explanation which are presented to us by what we know of the physiology, and disordered physiology, of the nervous system, in attempting to explain conditions met with in this and similar diseases.

Dr. James Stewart, of Montreal, said in connection with the influence of peripheral irritation, that in the cases of dilatation of the stomach where tetany had caused death, the symptoms came on a few hours after the stomach had been washed out. This would point to irritation rather than decomposition as the active cause in this class of cases. There are many other cases where infection could not enter.

Dr. John T. Carpenter, of Pottsville, Pa., said, in regard to anæmia as the cause of tetany, that we should have to go back of the anæmia to the cause that produced it. He knew of no cause that would produce anæmia so surely as septic absorption.

Adjourned.

---

Afternoon Session.

Dr. A. B. Ball, of New York, read a paper entitled

THROMBOSIS OF CEREBRAL SINUSES AND VEINS.

The author first referred to the influence of the following factors in the production of thrombosis: 1st, blood stasis;

2d, vessel lesions; and 3d, blood changes. The anatomical conditions in the sinuses that favor thrombosis were described at length; and a number of cases cited of marantic thrombosis of cerebral veins and sinuses in chlorotic girls.

The symptoms were next considered. Much importance has been attached to distention of external veins collateral to the internal veins supposed to be affected, giving rise to hemorrhages and œdema. These signs are frequently absent, and may be due to other conditions. The mobility of the symptoms has been considered of value. In these cases the cerebral symptoms undergo strange alternations, not seen usually in other affections. Active delirium is exceptional. The depression continues, but alternates with a certain amount of improvement. Fever is absent at first, and, if present, is to be attributed to complicating conditions. Paralytic symptoms, of varying extent, are usually present. With the exception of the variation in degree, the paralysis does not differ from paralysis from other causes.

DISCUSSION.

DR. WILLIAM OSLER, of Baltimore, exhibited two specimens illustrating the conditions described by Dr. Ball. The first specimen was one of extensive thrombosis of the lateral sinus, occurring in a man who died from phlegmonous erysipelas of the cheek. There were no special symptoms in that case.

The second specimen was from a woman dying of consumption. It was thought that gradually increasing coma, and the onset of cerebral symptoms, were supposed to be due to basilar meningitis.

DR. A. JACOBI, of New York, enumerated certain additional aiding causes. The first was a disproportion between the white and red blood-corpuscles. The second cause was the relative absence of muscular tissue in a number of the veins. A third cause was absence of water in the blood, often due to the withholding of sufficient fluid in the diet of patients. The last cause referred to was weakness of the heart. When in exhaustive diseases the heart is allowed to become feeble, thrombosis, with all its bad results, must be expected. It is certainly a good therapeutic measure to stimulate and strengthen the heart in every disease that will last long, or tends to terminate in exhaustion.

DR. WILLIAM H. WELCH, of Baltimore, said there is one point of great force in explaining the production of thrombosis, that is, the possibility that there is some form of intoxication analogous to that produced experimentally by various substances, such as the fibrin ferment. Under such circumstances there is almost instantaneously extensive thrombosis, wherever the ferment reaches. Pathologists are aware of the frequency with which thrombi, usually of a mixed character, are found in the cerebral sinuses, particularly the superior longitudinal sinus, in cases that have presented no symptoms during life.

DR. SAMUEL C. BUSEY, of Washington, D. C., read a paper entitled

THE EFFUSION OF CHYLE AND OF CHYLE-LIKE, MILKY, FATTY FLUIDS INTO SEROUS CAVITIES.

The object of the paper was to present the subject of effusion of chyle, chyle-like, and fatty fluids into serous cavities. It was limited to the effusion of such fluids into the cavities of the pleura, peritoneum, and tunica vaginalis. The subject of traumatic injuries of the absorbent vessels seems to have been peculiarly attractive to many of the older writers. Ruysch, as early as 1665, drew attention to wounds of the lymphatic vessels. The reported cases of effusion of chyle and milk-like fluids into the pleural and peritoneal cavities, including the doubtful cases, do not exceed forty-three, and these cases cover a period of one hundred and ninety years. Nevertheless, twenty-three cases of effusion of chyle and chyle-like fluids into the abdominal cavity have been observed during the present century—fifteen since 1850, and thirteen during the last and present decades. The increasing frequency of the occurrence is thus clearly shown.

*Effusion into the Pleural Cavities, Chylo-thorax.*—Of this, including the doubtful cases, there have been ten cases reported. In five of these the chyle poured directly from the thoracic duct. The diagnosis in these cases can only be made by evacuation and examination of the fluid. The prominent symptoms are dyspnœa and accumulation of fluid in one or both cavities. The prognosis is unfavorable and the treatment expectant.

*Effusion into the Tunica Vaginalis Testis.*—The case of galactocele reported by Vidal (de Cassis) seems to have been the first observation of this class of effusions. In two of the reported cases the patulous orifices of the vessels from which the lymph exuded were found. Since 1885 there have been reported in this country thirteen cases in which filaria were found, and two of these were cases of lymphocele. It has not been shown, however, that filaria are present in every case of lymphocele. It is conceivable that adenitis, gonorrhœal lymphangitis, or other conditions which obliterate the permeability of neighboring and connecting glands, might cause stasis of lymph and dilatation and rupture of lymph capillaries and plexuses, with which the serous membranes are so richly supplied. The opinion of those who have had the best opportunity to study the relation of filaria to disease in general seems to be that of Sir Joseph Fayres, that "it has been shown that disorders of the lymphatic system are most frequently associated with, if not caused by, the filaria. The recent invasion of portions of the subtropical belt of this country by the filaria, and the reports of cases of disease with which the parasite has been so uniformly associated, together with the fact that the mosquito has been proven to be its intermediate host, present considerations of the highest importance to the profession and general public. Some of the cases have been cured by injection of iodine, others have been cured by dissecting back the vessels and tying the bundle *en masse* with a silk ligature.

*Chylous and Oily Ascites.*—A tabulated statement arranged chronologically, presenting a condensed summary of the reports of cases of chylous and oily ascites, was given. The number of cases reported was thirty-three; primary rupture occurred in but five cases. Chylous ascites may be the secondary result of a variety of morbid conditions which directly or remotely obstruct the flow of the chyle through the lacteals, receptaculum, or thoracic duct, impede its exit into the left subclavian vein, or retard the current of blood in the left subclavian vein, right side of the heart, or lesser circulation. The relation of puerperal conditions to the effusion of chyle are not susceptible of explanation. In five cases the fluid found in the peritoneal cavity was associated with tuberculosis, and in four it is stated that the peritoneum was more or less studded with tubercle. No perforation or rupture of chyle-conveying vessels was found in any of these cases. The symptomatology of effusion of chyle into the peritoneal cavity is not sufficiently distinctive to differentiate such cases from ordinary ascites, and a diagnosis is only possible after examination of the evacuated fluid. Of the thirty-three cases, nineteen died, nine recovered, and in five the result is not stated. Of the twenty-two cases of chylous ascites proper, twelve died, five recovered, and in five the result is not stated. Meagre and unsatisfactory as are the clinical details of these cases, they point to two conclusions: first, that a free and unobstructed channel of communication between the venous system and the chyle-conveying vessels is essential to the proper nutrition of the body and preservation of life; and second, that death following the partial or complete obliteration of this communication is the result of inanition.

In seventeen of the thirty-three tabulated cases, tapping was practised, and, in most of the cases, repeated several times. Six of these recovered. In two laparotomy was resorted to, with recovery of both patients. One was a case of intact retention cyst, and the other was probably a ruptured cyst. As a medical resource, paracentesis is of questionable value. The treatment is mainly directed to the prolongation of life. The causative condition may in

some cases be amenable to medicinal treatment, but in most cases some surgical procedure might offer a prospect of cure. In filarial cases the treatment applicable to such would be admissible. Sonsina thinks that astringents, such as gallic acid and tincture of the chloride of iron, with rest, tonics, and proper alimentation, are useful. Lancereaux thinks that the parasitic forms of lymphatic diseases are curable. He has found mercurial inunction in the region of the affected gland, in connection with hydropathy, of service. He suggests the injection of parasiticides into the affected glands for the purpose of destroying the female adult worm.

DISCUSSION.

Dr. William Osler, of Baltimore, said that in ordinary post-mortem work it was not infrequent to meet with varices of the chyle vessels of the mesentery covering the walls of the intestine. Sometimes there are extravasations which may form large chylous cysts.

With reference to chyluria, he was positive that there was a non-parasitic form. He had made thorough examinations in one such case, and failed to find filaria. On post-mortem examination nothing was discovered. Also, in a case of lymph scrotum, he had examined the fluid and the blood, and had found no embryos. He laid a great deal of stress upon these cases, as it is generally stated that these conditions are always parasitic.

Dr. William H. Welch, of Baltimore, exhibited a specimen of chyle removed from the abdominal cavity of a boy twelve years of age. He described the chemical and microscopical characters of the fluid, and dwelt upon the importance of distinguishing between chylous and fatty hydrops.

Dr. J. F. A. Adams, of Pittsfield, Mass., read a paper entitled

SUBSTITUTES FOR OPIUM IN CHRONIC DISEASES.

The disadvantages attending the use of opium are: 1, In an overdose it is a poison; 2, in ordinary doses its benefits are largely offset by various functional derangements; 3, its use involves the danger of the opium habit.

*Remedies that may be Substituted for Opium for the Relief of Pain.*—The antipyretics—antipyrine, acetanilide, phenacetine, and exalgine—have well-grounded claims to be regarded as rivals of opium. They are, however, less certain and less prompt, particularly when pain is very violent. Antipyrine, in five- to ten-grain doses, had been found valuable as an analgesic, particularly in headache, neuralgia, and rheumatism.

Acetanilide he had found less active than antipyrine; he used it in doses of seven or eight grains. He had found it particularly serviceable in lumbago and dysmenorrhœa. In the latter condition one or two doses had afforded prompt relief.

Salicylic acid and its sodium salt should be included on account of their marked effect in the relief of pain in rheumatism, particularly its acute form.

*Substitutes for Opium to Induce Sleep.*—Paraldehyde is an excellent hypnotic, although rather uncertain. Hydrate of amyl is generally preferable to paraldehyde, being more reliable as well as more agreeable. Sulphonal is more extensively employed than either of the above, and is applicable to all forms of insomnia.

*Chronic Diarrhœa.*—It is probable that no remedy has been used in this affection so largely as opium. The effects of this mode of treatment have been far from satisfactory. Recently the author had treated these cases antiseptically, with far better results. The remedy chiefly used has been salicylate in five- to ten-grain doses, three or four times a day. He had also used salol with success.

We now have remedies which may be used in place of opium in all chronic affections, where formerly this remedy was our chief reliance. For producing sleep, and for the treatment of chronic diarrhœa, we have certain hypnotics and antiseptics which are not only as efficient, but so much more satisfactory, that we may practically lay aside opium, to be used only on rare occasions. As an analgesic opium still stands at the head of the list for promptness and certainty, but the antipyretics mentioned are probably capable of replacing it in the majority of chronic cases, and the relief afforded by these remedies is attended with less disturbance of the system than that induced by opium.

DISCUSSION.

Dr. G. M. Garland, of Boston, referred to the value of the fluid extract of gelseminum as a substitute for opium. In frontal headaches it has an admirable effect. It is used also with advantage in difficult and painful menstruation, and certain forms of neuralgia. As a simple hypnotic gelseminum answers well in cases of temporary congestion with insomnia and headache. In hysterical conditions, this agent will often induce sleep in a short time. The drug is given in doses of five to ten drops every half-hour, until the desired effect is obtained, or its physiological effect is produced in diplopia and plasis. These appear sufficiently early to serve as a warning.

Dr. Israel T. Dana, of Portland, reported two cases of opium habit occurring in a man and wife. The husband was a young man who had for some time given hypodermic injections of morphia to a patient dying of cancer. He subsequently broke his leg, and remembering the effect of the injections in the case of cancer, he tried them on himself. The result was so exhilarating, and as he "could not see why his wife should not have a little of the fun," he began giving her the injections, although she was perfectly healthy. In this way the habit was induced, and when admitted to the hospital each one was taking six grains of morphia daily.

Dr. M. G. Dadiman, who had practised in Asia Minor and Constantinople, stated that he had never seen a case of opium habit in his practice in these places.

Dr. D. W. Prentiss reported a

REMARKABLE CASE OF SLOW PULSE,

ranging from thirteen to forty per minute, continuing for two years, without organic heart disease, in a man of fifty-seven years, in otherwise good health. The cause was supposed to be tobacco poisoning, the man being an inveterate smoker, or malarial poisoning, or perhaps both. The report was supplemented by a review of such similar cases as the literature of the subject affords. The principal interest in the case turns on the pathology—whether the slow pulse is due to over-stimulation of the inhibitory nerve, or to paralysis of the sympathetic, or to lesion in the nerve-centres. The treatment in the case has been addressed chiefly to stimulation of the sympathetic. The patient was presented to the inspection of the Association.

SECOND DAY, THURSDAY, SEPTEMBER 19TH—MORNING SESSION.

Dr. Frederick P. Henry, of Philadelphia, read a paper on the

RELATION BETWEEN CHLOROSIS, SIMPLE ANÆMIA, AND PERNICIOUS ANÆMIA.

The discussion of the relation between chlorosis, simple anæmia, pernicious anæmia, etc., may be divided into three heads:

1. Are they separate diseases?
2. Are they of kindred nature?
3. Are they different stages of one affection?

Pernicious anæmia is first considered, because the determination of its status is of fundamental importance. It is admitted by all that the clinical features of this disease are common to a number of affections, especially cancer and atrophy of gastric glands; but those who argue most forcibly in favor of its independent nature exclude from the category of pernicious anæmia all cases in which an anatomical lesion of any organ is found. This appeared to the author unscientific, for an independent disease is one

which rests upon a constant anatomical basis or is invariably produced by the same specific agent. Hunter has endeavored to establish pernicious anæmia as an independent disease by the demonstration of an excess of iron in the liver in cases of that affection. He regards this as the essential anatomical feature of pernicious anæmia. The work of Hunter is of great value, and certainly demonstrates the existence of an excessive hæmolysis in that disease. In the author's opinion, however, this excessive hæmolysis is a consequence of defective hæmogenesis, for certain facts show the red corpuscles of pernicious anæmia to be abnormally weak and perishable. Chlorosis is universally admitted to be due to defective hæmogenesis, and therefore he regarded it and pernicious anæmia as closely related affections. Transitions from the one affection to the other had also been observed by himself and others.

Conclusions: (1) That pernicious anæmia is a process, not a disease; (2) that it is closely related to chlorosis; (3) that it may be the terminal stage of other diseases, and especially of cancer of the stomach and atrophy of the gastric glands.

Leucocythæmia and Hodgkin's disease, in that they are always associated with lesions of the blood-making organs —spleen, lymph-glands, bone-marrow, etc.—are independent diseases, or, rather, different stages of the same disease, for several cases are recorded in which an undoubted transition from one to the other has been observed.

Dr. F. Forcheimer, co-referee, of Cincinnati, read a paper entitled

THE RELATIONS OF ANÆMIA TO CHLOROSIS.

The speaker first referred to the confusion which existed in regard to the definition of the two diseases. Immermann states that we are justified in saying that anæmia is that condition in which there is a diminution of red corpuscles as well as of the albumins of the plasma in the blood (hypalbuminosis). Strümpell considered that "the essential element in anæmia is therefore a diminution in the number of red corpuscles or so-called oligocythæmia," and states further that "oligocythæmia is not invariably accompanied by a diminution in the amount of serum-albumin (by which he means plasma—hypalbuminosis)." Going on, it is found that anæmia or oligæmia vera really means a diminution of the quantity of the blood, and that this condition can be divided into hydræmia, oligocythæmia, oligæmia sicca, and oligæmia hypalbuminosa. We have three representative definitions; the one broad and general, including a diminution of any one or all of the constituents of the blood; a second, in which hypalbuminosis and oligocythæmia are the principal, if not the only, factors; and a third, which makes oligocythæmia alone the characteristic feature. From a purely practical stand-point the latter seems the best.

The same confusion in regard to definition is met with in a consideration of chlorosis. Duncan (1867) was, however, probably the first to make the distinctive feature, oligochromæmia, characteristic for chlorosis—that is, in chlorosis we find the individual red corpuscle deficient in hæmoglobin. Unfortunately for this definition, the term chlorosis is to be looked upon as an essentially clinical one; it is not going too far to state that by far the great majority of reported cases of chlorosis are not chlorosis at all. Another difficulty is that both oligocythæmia and oligochromæmia may occur in the same individual, so that the term chloranæmia is justified by observation of existing conditions. It is more than probable that anæmia is a forerunner of chlorosis in a great many instances, and possibly a number of cases occur in which there is a combination of both conditions.

Almost every cause put down for anæmia will hold good for chlorosis. Sex, age, a peculiar composition of the blood, and certain vascular anomalies are held to be especially characteristic for chlorosis. The two latter are the only ones to be found in chlorosis. The process of sexual development is looked to as the time of most common occurrence of chlorosis. This age also produces a great number of cases of anæmia; but children and old people are subject to anæmia and practically excluded from chlorosis. The greatest number of cases occur between the ages of fifteen and twenty-five years, decidedly after the time of first menstruation. Furthermore, an anæmic constitution is a strong predisposing cause for chlorosis.

The clinical characteristic of chlorosis lies in the peculiar changes in the blood. In anæmia the red corpuscles, as well as the albumins of the plasma, are reduced in quantity, and frequently there is production of a greater number of smaller corpuscles (microcytes). As a result of the reduction of the number of red corpuscles the plasma is correspondingly reduced in quantity. In pure chlorosis the number of red corpuscles is not diminished, and a tendency to the production of larger red corpuscles (megalocytes) is especially well-marked. These changes are, however, not sufficiently characteristic to establish a diagnosis. It is also found that the amount of plasma in each corpuscle is diminished. It has been said that in anæmia there is always hypalbuminosis, while in chlorosis this is absent, but this has not yet been positively proven.

One respect in which chlorosis is said to differ materially, if not absolutely, from anæmia consists in the pathological changes, first described by Virchow. These are narrowing of the lumen of the aorta and larger arteries as well as thinning of their walls. The heart is sometimes small, sometimes hypertrophied. This view would permit us to state that chlorosis is always congenital, in some cases latent for years, while anæmia, in most cases, is acquired. Many objections have been urged against this view.

The relation of the symptoms of anæmia to chlorosis depends upon the condition of the blood and the anatomical substrata. Given a case of anæmia in which there is only a reduction of plasma as a result of oligocythæmia, and a case of chlorosis in which there is a reduction of plasma as a result of oligochromæmia, and metabolism in both these cases will be approximately the same; but if in anæmia we have oligocythæmia as well as hypalbuminosis, which is said to coexist in the majority of cases, the metabolism must be different from that of a pure case of oligocythæmia. As a result of reduction of plasma there is simply reduction in the process of oxidation; at the same time the waste products are carried off and sufficient albuminous food is carried to the tissues by the plasma of the blood, which is unchanged. Hypalbuminosis and oligocythæmia produce an entirely different result; we have the same factor, suboxidation, but we have in addition deficiency of supply. In mild cases of anæmia, there is procuced a loss of weight; in severe cases, the condition called marasmus. In chlorosis very little, if any, loss of weight occurs; very frequently the opposite condition is brought about by too great supply and by the presence of too much $CO_2$, preventing decomposition of fats. When anæmia is associated with chlorosis, we have a very unfortunate combination, especially if there is a great amount of hypalbuminosis.

Unless we believe that the anatomical lesions of Virchow belong to chlorosis, there exists no difference between the symptoms of chlorosis and anæmia.

The therapeutic relations of the two diseases must be considered. While the indiscriminate use of iron in anæmia must be deprecated, yet upon the whole iron is just as much looked upon as a specific in anæmia as in chlorosis. Where in anæmia we try to remove the cause and institute causal treatment, we are satisfied in chlorosis with removing that symptom which is the essential of the disease. It has been repeatedly demonstrated that the removal of this essential symptom is followed temporarily by complete recovery. Whereas, in anæmia, treatment is followed by complete recovery or complete failure, iron in chlorosis will always result in amelioration, even if the tendency to relapse cannot be removed. There are few cases of chlorosis, even those with the lesions of Virchow,

that are not benefited by the administration of iron in sufficient quantity. In a great many cases of anæmia, the use of iron would be followed by negative, or by bad, results.

DISCUSSION.

Dr. William Osler, of Baltimore, took issue with Dr. Henry in regard to chlorosis. He held that chlorosis is absolutely distinct from pernicious anæmia, and for the following reasons: 1. The sex; he had never seen chlorosis in the male. 2. The pathological conditions; he regarded thus the hyperplasia of the heart and great vessels as a specific anatomical distinction of a certain number of cases. 3. The characters of the blood; he considered the diminution of the percentage of hæmoglobin a distinctive feature of chlorosis. 4. Curability; although in chlorosis there is a tendency to relapse, each given attack can be cured if sufficiently large doses of iron are employed.

Dr. Francis P. Kinnicutt, of New York, agreed with Dr. Osler as to the lack of relation between chlorosis and pernicious anæmia. He had never seen true chlorosis in the male. All his cases of pernicious anæmia, on the other hand, with one or two exceptions, had occurred in males. He agreed with Dr. Henry in regard to the relationship between Hodgkin's disease and true leukæmia. He reported a case which came under his observation, with typical symptoms of Hodgkin's disease. At this time the proportion of white corpuscles to red was normal. The spleen and liver gradually enlarged, and two years later, at the time of the patient's death, there was one white corpuscle to five or six red.

Dr. W. W. Johnston, of Washington, thought that a study of certain anæmias which are met with in women will throw light upon the association of anæmia with diseases of the intestinal glands and gastric tubules. The explanation of the chronic anæmias of parturition is probably the continued pressure upon the intestinal tube, causing a long starvation lasting nearly a year. This seems to produce an actual organic change in the intestinal glands. Several illustrative cases were cited.

Dr. William Pepper, of Philadelphia, agreed with Dr. Osler in regard to the relation between true anæmia and chlorosis, and progressive pernicious anæmia so called. He was not prepared to admit the analogy between true chlorosis and progressive pernicious anæmia. The conditions of the blood are widely antagonistic in these two affections. The clinical differences are also very marked. In the present state of knowledge it is probably wiser to consider essential anæmia as an independent affection.

Dr. Frederick P. Henry, of Philadelphia, thought that the definition of chlorosis given by Dr. Osler could not be maintained; that is, that there is always a diminution of hæmoglobin with a nearly normal number of red corpuscles. The arguments that he had advanced were based entirely upon personal observations. While chlorosis is readily relieved by treatment in the early stages, yet, if it is neglected, the chlorosis may become more intense and may present the appearances of pernicious anæmia.

Dr. S. Weir Mitchell, of Philadelphia, read a paper entitled

SUBJECTIVE FALSE SENSATION OF COLD, CONSIDERED AS A SYMPTOM.

The speaker had met with many cases where a feeling of cold is complained of in members which do not present any objective changes in temperature. These may be placed in three classes: 1, those due to a central cause; 2, those due to neuritis; 3, those whose origin is at present inexplicable, or due to hysteria. A number of cases exhibiting this symptom to an extreme degree were reported. In the first case a marked sensation of cold involving the left side of the body followed an injury to the head. Three or four cases were referred to coming in the second class. The sensation of cold involved the posterior part of the legs, the back, or buttocks. In all these cases there was either neuritis at the time, or it developed subsequently. When this symptom is noted, neuritis may be expected. Two cases belonging to the third group were described. One was an elderly individual with no sign of hysteria, the other was a case of a young woman with marked hysterical symptoms.

DISCUSSION.

Dr. James J. Putnam, of Boston, had frequently seen the coldness spoken of in chronic spinal disease and in neuritis, and described such a case in a man with chronic sensory neuritis.

Dr. F. T. Miles, of Baltimore, regarded this sensation of coldness as a very important symptom of neuritis, and reported a case associated with acute neuritis of the ulnar nerves.

Dr. G. M. Garland, of Boston, read a paper on

GASTRIC NEURASTHENIA.

The author first reviewed Leube's observations on dyspepsia nervosa, and presented a category of the gastric neuroses. A case of anorexia nervosa occurring in a woman sixty-three years of age was reported. The woman was of feeble constitution. She digested her food without consciousness of the process, and her bodily functions were practically normal in every way, except that she suffered from anorexia. Three cases of vomitus nervosus were then reported.

Case I.—Miss S—— began, at the age of two years, to have certain attacks of vomiting. These recurred at certain intervals until the time of her death. The attacks lasted twenty-four hours, and it required a week for the child to recover her strength. At the age of twenty she began to have excessive muscular twitchings with the attacks. Two years later she began to have severe headaches. These gradually merged into one steady ache. January 1, 1884, the author saw the patient suffering from intense headache and slight twitching of arms and legs. Vomiting appeared the next day, causing intense burning of the throat from the intensely acid character of the matters vomited. After four days she gradually improved, and entirely recovered.

November 12, 1884.—The patient was again seized with headache. November 15th.—Vomiting and twitching began. She gradually improved until December 2d, when all the symptoms returned and continued until her death, December 13th. Urine was normal until a few days before death, when it contained a trace of albumen, but no casts. At the autopsy no marked organic change was found in any part of the body.

Case II.—Miss S——, aged twenty-two, first seen September 19, 1888. She was in bed with headache, poor appetite, constipation, and weakness. Pulse, temperature, and urine normal; some nausea. Vomiting appeared in a few days. She was fed exclusively by the rectum for three weeks, but the vomiting persisted, and there was severe burning along the entire œsophagus. At times the urine was scanty, but never contained albumen. She gradually improved, but is not as strong as before her illness.

Case III.—Miss D——, aged forty-three, had been subject to bilious headaches. During the summer of 1888 she had a severe attack of vomiting, and she was very ill for several weeks. During the following September, as a result of anxiety, her appetite left her and the nausea returned. She, however, did not vomit.

The conclusions drawn from the above cases were: 1. All the women have been of dark complexion. 2. They have not been of the so-called hysterical temperament. 3. Feeding by the mouth was abandoned in every case, and rectal enemata were necessary. 4. None of the drugs usually potent in soothing a nauseated stomach were of any avail. Morphia subcutaneously was the only remedy that was of benefit. 5. The vomitus caused great discomfort along the throat, and in one case caused severe glossitis. In connection with the hyper-acidity, he referred to certain

cases of acid vomiting described by Rossbach, and designated nervose gastroxynsis. The acidity of these cases depends upon excessive secretion of hydrochloric acid, and is independent of the presence of food in the stomach.

---

AFTERNOON SESSION.

The discussion of Dr. Garland's paper was taken up.

DR. S. WEIR MITCHELL, of Philadelphia, said that in all cases of neurasthenia, where there are great complaints of gastric and intestinal difficulty, the presence of hypochondriacal conditions must constantly be considered. It is rare for grave cases of neurasthenia to present themselves without some abdominal symptoms. In regard to anorexia nervosa, he thought that in the majority of cases a background of hysteria would be found. It is suspicious that this condition is never seen in men.

DR. WILLIAM PEPPER, of Philadelphia, asked in what respects, other than the invariable and extreme acidity of the matters vomited, these cases differ from those that have been described under the head of cyclic and recurrent vomiting. He had seen many such cases and some like the fatal case reported. In some of the cases the vomited matters were extremely acid. He had had these matters examined chemically with the hope of finding some leucomaïne, but so far with negative results. In regard to treatment the only remedy that had been of benefit had been antipyrine. In one or two cases this has apparently stopped the attacks.

DR. W. F. WHITNEY, of Boston, presented specimens from two cases of cretinism.

DR. JOHN H. MUSSER, of Philadelphia, read a paper entitled

PRIMARY CANCER OF THE GALL-BLADDER AND DUCTS.

The speaker, after describing two cases of this affection that had come under his observation, reviewed the cases that had been reported and presented the following conclusions:

Primary cancer of the gall-bladder is not so rare as is generally believed. It occurs in the female nearly three times as often as in the male. A large number, fifty-seven per cent., of the cases occur under the age of sixty. Gall-stones are an exciting cause, especially in persons predisposed to the affection. The organ is generally not much enlarged, save as the result of secondary processes. Metastasis is not wide-spread. By continuity of structure neighboring organs are involved. Adhesions to adjacent organs, with ulceration and perforation, are not uncommon. Pain, jaundice, and the presence of a tumor are the most common phenomena. With them are associated cachexia, vomiting, constipation, diarrhœa, and ascites. Pain was present in sixty-two per cent. of the cases, at first ill-defined, then becoming localized to the right hypochondrium, and lancinating in character. Jaundice was present in sixty nine per cent., gradually increasing in degree. In some cases, however, it was intermittent. Tumor was noted in sixty-three per cent. The tumor was hard, firm, painful, and generally movable with respiration. The progress of the disease is always continuous. Some extraordinary cases are reported in which there was temporary cessation in the progress of the disease. Death results from exhaustion, frequently from peritonitis, in some cases from metastasis to other organs, in some from biliary obstruction. In eight cases death was due to cholæmia. The duration of the disease is short, the average being six and two-third months. The progress is rapid after complete occlusion of the biliary passages, or evidence of inflammation of the biliary passages has developed.

DR. HENRY FORMAD, of Philadelphia, read a paper on

THE ANATOMICAL AND PHYSIOLOGICAL RELATIONS OF LESIONS OF THE HEART AND KIDNEYS.

The paper was based upon the post-mortem study of three hundred cases, observed in public and private practice.

DR. P. G. ROBINSON, of St. Louis, read a paper entitled

THE CONTAGIUM OF DIPHTHERIA.

The subject is one which merits our most earnest and continued study, because of the prominent place it occupies among the prevailing causes of annual mortality, and because of the diversity of opinion which is entertained in regard to its etiology, pathology, and treatment. The disease has become familiar to the practitioner only within the last generation, although traced historically to a very remote period. It prevails very generally throughout this continent, and constitutes one of the chief and most constant causes of mortality, which amounts to nearly one hundred and twenty five per thousand of the population of the United States, and of cases reported the percentage of deaths is from thirty to thirty-five.

Diphtheria is an acute infectious disease, doubtless due to a living organism (microbe) the exact identity of which cannot yet be regarded as settled. Primarily a local affection, the system becomes secondarily and generally infected through absorption of a poison generated at the primary and localized seat of inoculation. The modes of infection are numerous, the contagium being directly transferred by contact, in a dry state, through the air for limited distances, in foul clothing, in polluted food and drink, milk probably being a prolific source of infection.

The most difficult problem to solve is that which relates to the conditions most favorable to the growth and development of the germs and the propagation of the disease.

While, strictly speaking, diphtheria can hardly be called a filth-disease, since it prevails often to a very limited extent in those localities whose hygienic surroundings are apparently the worst, yet certain kinds of filthy accumulations, as the ordure of animals, notably the refuse from cow-sheds and dairies, seem to furnish the most favorable conditions for the culture of this particular germ. Until this problem can be solved and the life-history and habitat of the diphtheritic germ is understood, no definite plan can be formulated for the arrest of the contagion nor for the hopeful treatment of the disease.

THIRD DAY, FRIDAY, SEPTEMBER 20TH—MORNING SESSION.

The following officers were elected:

*President*—S. C. Busey, of Washington; *First Vice-President*—William Pepper, of Philadelphia; *Second Vice-President*—Henry U. Lyman, of Chicago; *Recorder*—I. Minis Hays, of Philadelphia; *Secretary*—Henry Hun, of Albany; *Treasurer*—W. W. Johnston, of Washington; *Member of Council*—G. Baumgarten, of St. Louis; *Representative on Executive Committee of Congress of American Physiciaus and Surgeons*—William Pepper, of Philadelphia.

MEMBERS ELECTED.

William G. Thompson, William H. Thomson, J. West Roosevelt, of New York; Charles Carey, Charles G. Stockton, of Buffalo; Victor C. Vaughn, Heneage Gibbes, of Ann Arbor; Charles W. Purdy, of Chicago; Starling Loving, of Columbus, O.; W. H. Geddings, of Aiken, S. C.; William C. Dabney, of Charlottesville, Va.; B. F. Westbrook, of Brooklyn; Henry P. Walcott, of Cambridge, Mass.

The date of the next meeting to be between May 20, and June 15, 1890.

DR. JAMES J. PUTNAM, of Boston, read a paper entitled

A SUPPLEMENTARY INQUIRY INTO THE FREQUENCY WITH WHICH LEAD IS FOUND IN THE URINE.

The paper embodied further researches as to the frequency with which traces of lead are found in the urine of persons in good health, or not presenting the classical symptoms of lead-poisoning; and discussed the propriety

of enlarging our clinical conception of that disease. A table was shown, in which the results of the present investigation were combined with those reported upon two years ago, which may be summarized as follows: The urines of sixty-eight persons, either presenting no symptoms (healthy medical students) or only symptoms of specific or local disease (phthisis, pleurisy, local injuries, etc.), were found by Dr. A. M. Comey and Dr. C. P. Worcester to contain lead in the proportion of about seventeen per cent.; while those of another group of one hundred and twenty-five persons, presenting various symptoms of disease, such as it was thought might possibly be due in part to lead-poisoning, contained lead in the proportion of fifty per cent. The largest sub-group of this latter class embraced thirty-six cases, not strictly homogeneous, but made up of chronic or subchronic affections of the spinal cord and peripheral nerves. One (typical) fatal case of this sub-group was analyzed at some length, and the results of the microscopic examination of the spinal cord and nerves were reported upon. The case was that of a carriage-painter, who suffered for some years with progressive anæmia and general emaciation, and for the two years preceding his death with weakness, paræsthesia, and impairment of sensibility, with exaggerated tendon reflexes and extensor spasm, increasing finally to complete paraplegia. Lead had been found in the urine three times, but the patient had never presented "a blue line," characteristic of paralysis, encephalopathic symptoms, or colic, though the bowels had been obstinately constipated for years. The morbid changes found after death, besides the signs of general anæmia, were those of combined antero-posterior and lateral sclerosis of the cord, on which at the last, a subacute process of diffuse destructive softening had engrafted itself.

This latter process, which was characterized by the presence of a dense infiltration of granule-cells, and by a breaking down of the nerve-tubes, so as to form round or oval cavities, such as have often been described, extended throughout the length of the cord, occupying the position of the sclerosed system tracts and the adjoining tissue. The nerve-roots were affected, though to a less degree than the cord; the posterior much more than the anterior. The acuter process was at its height in the dorsal region. The gray matter was also affected, apparently in proportion to the severity of the secondary acute change, *i.e.*, most severely in the dorsal region. The smaller arteries were here and there thickened. The peripheral nerves were degenerated, but only to a moderate degree.

It was not assumed that these changes in the cord were due to lead as a specific poison, though at the same time the evidence is that such myelitic changes as lead does set up are diffuse in character and not co-ordinated with the typical peripheral nerve-degeneration. It was, however, thought more probable, in view of the circumstance under which such pathological processes had been seen in other cases, that the lead acted, if at all, by inducing a general and—through the thickening of the vessels—a local anæmia, thus intensifying the effects of other influences, of which one might be an hereditary tendency.

Another case was cited to show that lead in drinking-water may cause outbreaks of acute indigestion in children, while other children exposed to the same influences may be wholly unaffected.

A number of observations made on Boston drinking-water, by Dr. E. M. Greene, were reported, showing the frequency with which lead is present and the length of time required to wholly rid a pipe of its presence.

Harold C. Ernst, of Jamaica Plain, Mass., read a paper entitled

HOW FAR MAY A COW BE TUBERCULOUS BEFORE THE MILK BECOMES DANGEROUS AS A FOOD SUPPLY.

The observations which he reported were made at the instance of the Massachusetts Society for the promotion of Agriculture. The surroundings of the animals and food were prepared in the most careful manner. One hundred and fourteen samples of milk were examined for the bacillus. These were obtained from thirty-six cows, suffering with tuberculosis of some organ other than the udder. Seventeen samples were found to contain tubercle bacilli. These seventeen specimens came from ten cows. The cream was found to contain bacilli as often as the milk. The bacilli were present with a fair degree of constancy.

Well animals were then inoculated, with the result of inducing the disease in fifty per cent. of the cases treated. Feeding experiments were also made with the result of inducing the disease in a number of calves and young pigs. The following conclusions were presented: 1, and emphatically, that milk from cows affected with tuberculosis in any part of the body may contain the virus of the disease. 2. That the virus is present whether there is disease of the udder or not. 3. That there is no ground for the assertion that there must be a lesion of the udder before the milk can contain the infection of tuberculosis. 4. That, on the contrary, the bacilli of tuberculosis are present, and centre in a very large proportion of cases in the milk of cows affected with tuberculosis, but with no discoverable lesion of the udder.

Dr. E. N. Whittin, of Boston, read by title a paper on

PRIMARY CANCER OF THE DUODENUM.

Dr. William Osler, of Baltimore, exhibited a patient showing anæsthesia the result of lesions of the cauda equina.

Dr. E. L. Trudeau, of Saranac Lake, read a paper entitled

HOT-AIR INHALATIONS IN PULMONARY TUBERCULOSIS.

The paper presented a brief clinical history of four cases treated during periods varying from one to four months by Weigert's method. This was considered as secondary, and only as a basis for the bacteriological study, which is left to answer the claim of specificity made for the method. The question to be answered is whether breathing of hot air can prevent the growth of the tubercle bacillus in the lungs of living individuals. The clinical evidence obtained brings out no positive proof in favor of the treatment. From the bacteriological research the following notes are made: In all the cases the bacillus which was present before the treatment remained in the sputum, and no effect was produced upon that important element of the disease. The claim of diminished virulence was tested by inoculations made on rabbits before, during, and after the treatment. The sputum of one of the patients, who improved, was found fifteen weeks after the uninterrupted daily breathing of hot air to produce tuberculosis in the animals injected, as promptly and to a similar extent as that injected before the treatment had been instituted.

*Conclusions.*—1. The therapeutic value of hot-air inhalations in phthisis is doubtful. 2. The evidence obtained by bacteriological study of the cases recorded does not confirm the assumption that inhalations of heated air can either prevent the growth of the tubercle bacillus in the lungs of living individuals or diminish the virulence of this microbe when it has gained access to them.

A Centenarian Surgeon.—The *Patria* of Buenos Ayres affirms that there is now in Bolivia a surgeon, Luca Silva by name, whose age is not less than one hundred and twenty-nine years. He was born in Cochabamba, in 1760, and devoted himself, after graduating in medicine, to the practice of surgery. He rendered important service to his country, when, after the famous manifesto of June 16, 1809, she entered on her struggle for independence. His treatment of the wounded, particularly his operations on the field of battle, won him high distinction. He also earned signal honor in the combatant ranks.

## BRITISH MEDICAL ASSOCIATION.

*Fifty-seventh Annual Meeting, held at Leeds, England, August 13, 14, 15, and 16, 1889.*

(Special Report for THE MEDICAL RECORD.)

(Continued from page 335.)

### SECTION OF MEDICINE.

FRIDAY, AUGUST 16TH—THIRD DAY.

THE proceedings of the Medical Section on Friday commenced by a paper by DR. RUFFER (Paris Institute of M. Pasteur),

#### ON THE PREVENTION OF HYDROPHOBIA BY PASTEUR'S METHOD.

DR. EDDISON, of Leeds, presided, and before calling on Dr. Ruffer to read his paper observed that he had for some time believed that it was useless to send hydrophobia patients to Pasteur. He had, however, gradually been compelled to change his mind on this point, as evidence became clear in the direction of this operation.

DR. RUFFER said that the disease hydrophobia had excited immense interest ever since the days of Aristotle. It was not a common disease, and many men of great medical experience had never seen a single case of it. The fact that a person bitten by a rabid dog was in danger of his life for a whole year was what made the disease such a terrible one, for hitherto there had been no chance of curing the patient when once attacked with symptoms of the malady. In 1885, in the month of November, M. Pasteur first stated that he could prevent hydrophobia in dogs, after they had been bitten, and this announcement was speedily followed by the treatment of human beings by this process which had proved successful in the case of dogs, and at the present time more than twenty establishments existed in Europe, and throughout the world, to carry out Pasteur's process. Hydrophobia was a specific infectious disease, which never, as far as was known, originated *de novo!* Unfortunately in this case, up to this date, no micro-organism had been seen which caused the disease. Experimentally, it had been found that inoculations in all parts of the body with the virus of rabies had power to produce the disease; but it was only when the virus was deposited beneath the dura mater, that the disease inevitably followed such insertion of it. It was found in the treatment by Pasteur's inoculation processes that abscesses never followed the inoculations. With regard to the incubation period of rabies, it was found that twenty per cent. of patients who succumbed to the disease died within a month after the bite, ninety per cent. died before the end of four months, and only a very small minority had an incubation of anything like a year. The longest incubation period he had been able to hear of was one where the patient succumbed fifteen months after the bite. The shortest incubation on record was thirteen days after the bite.

The second stage in the attack was the convulsive stage. Hydrophobia was a bad name for the disease, since the symptom of aversion to drink might be absent throughout the whole course of the disease. In dogs this symptom was usually absent. In rabbits there was no agitation, but simply paralysis seen. Some human beings died of the paralytic form of the disease, and Dr. Gamaleia had narrated twenty cases of death occurring in Odessa from this paralytic form of rabies, which was now known to be a far more frequent form of the disease than was formerly supposed. Hydrophobia or rabies was always fatal in man, but not quite so uniformly fatal in dogs. Thus M. Pasteur found one dog out of three which he inoculated with rabies which had only a mild attack of rabies, and then recovered completely, and was then quite safe against all inoculations after that event. If a rabbit be inoculated by a rabid dog's virus, that rabbit would die in eighteen days, but if a piece of the spinal cord of that rabbit were inoculated under the dura mater of a second rabbit, it would die in fourteen days; a third rabbit treated from the second rabbit would take the disease on the ninth day, and at length rabbits inoculated under the dura mater would take the disease invariably on the sixth or seventh day, and die on the tenth day. This was the so-called "fixed" virus of M. Pasteur, and was uniform in its strength for years if inoculations were carried on uninterruptedly on fresh rabbits. If the spinal cord of such animals, after death, were hung up in a dry sterilized bottle, the virus gradually, and in eleven days, lost its virulence. If a piece of such an exhausted spinal cord were injected into an animal, the poison of the special microbe was injected into that animal. In the case of the yeast-plant, it died when it had produced a certain quantity of alcohol and carbonic acid in any medium; and all germs produced certain poisons in which they could not exist if there were much of them. If the germ of malignant œdema were cultivated in beef-tea, and if the sterilized fluid were injected into a guinea pig, and then into a dog, the dog would die; but if the poison of the germ were injected beforehand, the dog would be safe. The animals were then said to be "vaccinated" against that virus. This was the explanation of the way in which the Pasteurian treatment of hydrophobia succeeded in preventing the outbreak of the fatal symptoms of the disease.

Pasteur had two treatments which he made use of at present in treating rabies in patients. The first was the simple method, the second was the intensive method. If the cord of thirteen or fourteen days were injected subcutaneously nothing but vaccinatory matter was injected, and after this if a few of the germs were injected along with this substance it was possible gradually to arrive at injections with the virus of the second or third day, when the patient was rendered unsusceptible to the effects of the virus of the dog-bite. The simple treatment lasted fifteen days, and on the first day the patient was inoculated with the cord of the fourteenth and thirteenth day, and so on, two injections being made daily for fifteen days. The intensive treatment was had recourse to for bites about the face, for in such cases an incubation of only thirteen days occasionally occurred. Here a large quantity of vaccinatory substance had to be injected quickly and repeatedly, and four injections were made daily for twenty days, two days' rest being given, after injecting a certain number of times, followed by resumption of inoculation until, in all, twenty days' inoculation were given.

Pasteur never injected the virus of the first or second day. As to the details of the operation, the occurrence of erysipelas was avoided by sterilizing the subcutaneous injecting needles by dipping them into boiling oil before using them. All of the injections were made in the abdomen, and no evil effects ever followed these injections. Supposing that a patient were bitten by a rabid dog, would he have a better chance after Pasteur's inoculations, than if he had not been treated at all? This required the consultation of statistics before and after this treatment had come into vogue. The statistics before the Pasteur process was invented were as follows: In Wurtemberg, nineteen per cent. of all patients bitten by rabid dogs or cats had died, and twenty-one per cent of those similarly bitten in Paris. The best statistics were those of Leblanc, who found that 15.9 of all persons bitten by rabid animals had died of the disease. All other statistics cited showed too high a percentage; but fifteen per cent. might be looked upon as pretty near the truth. As to bites of rabid wolves, the statistics published gave a mortality of from sixty to sixty-four per cent. after these; but, in many cases, the percentage was still higher. Thus Menchikoff, of Odessa, mentioned that a rabid wolf bit thirty-five men and twenty-three women, and that twenty four of the men died and fifteen of the women. Seventy-seven per cent. of the cases had died. But of people bitten in the face by such wolves, eighty-eight per cent. were said to have died. Leblanc's tables give a mortality in wolf-bites of this character of eighty per cent.

As to the statistics of Pasteur's laboratory, the cases were divided into three groups. In the first group were those patients who had been bitten by dogs found to be mad by the examination of their brain, in the second the cases where the dog was certified to be mad by veterinary officers, and in the third were the cases where the dogs were reputed to be rabid. The result of the statistics up to the present date was that there was a percentage of 1.4 deaths among persons bitten in the first group, and of .58 in the cases when the dog was not supposed to be mad. When the simple treatment was still used the mortality in cases of bites on the hand and face by rabid dogs was 4.83; but since the intensive treatment had been applied, fifty cases bitten on the face and head had been treated without a single death. The percentage of deaths after bites on the hand had been 1.22 per cent. In other countries the statistics were also very favorable. In St. Petersburg, from 1886 to 1888, the mortality had been 2 per cent. of all treated by Pasteur's process. In Odessa, where this simple treatment was applied the death-rate was 3 per cent. When the intensive treatment was applied, in 1887, it was only .58 per cent. and in 1888 .6 per cent. Lately, of twenty-six cases treated there one child aged seven died, although all the patients had been terribly bitten by wolves, and one of them had thirty deep wounds. In Moscow, in 1888, the mortality was only 1 per cent. In Varsovie a medical man, a pupil of Dr. Koch, and at one time opposed to the preventive treatment, had treated three hundred and seventy persons by it and they had all escaped. In Italy, at Turin, the percentage had fallen to .56 and in Naples Dr. Cantani reported a mortality of from 0 to 1 per cent. Pasteur's statistics up to 1887 showed a total mortality of 1.37 per cent. Of 1,501 patients bitten by dogs proved to be rabid there was a mortality at first of 1.52 which, afterward fell to .95 per cent. and in 1888 to .55 per cent. It had been asserted that, instead of preventing hydrophobia, Pasteur's inoculations had caused a certain number of deaths from the disease. This was a complete error. No such case had been seen, whereas numbers of the assistants in the Pasteur Institute and of the pupils of Pasteur in foreign countries had such confidence in the process that they had inoculated themselves preventively, because, being constantly in the midst of the redoubtable poison, they considered it important to "vaccinate" themselves in case of accidental inoculation of the parts. And when it was alleged that the cases which had died after Pasteur's inoculations had been of the paralytic type this was not of any importance, as that type was every now and then seen in the course of the natural history of the disease.

Dr. Eddison, of Leeds, in opening the discussion, said that in Leeds there had been two great epidemics of hydrophobia, or rather of rabies, the latter of which names was far the most scientific. He had seen many cases of the disease in the Leeds Hospital, *i.e.*, at least twenty. Some persons would have it that there was no such disease, and a great teacher in Leeds taught this erroneous doctrine for many years, and confused many of his pupils by so doing. He asked Dr. Ruffer whether in the case when one dog recovered after inoculation of rabies, it was reinoculated with the same virus or not. Were wolf-bites worse because the animal was in the height of its disease and thus bold enough to enter villages. In criticising the results of Pasteur's treatment, this should be done as was done in criticising the results of treatment by any surgical operation or poison. In such cases it was not said that the patient died of the treatment, but the aim was to find how many persons were saved by it.

A Member said he lived in Hertfordshire, and had recently sent a boy to Pasteur's Institute who had been bitten by a mad dog in his neighborhood. He had also visited the Institute and seen one hundred and fifty persons under treatment.

Brigade-Surgeon Dwyer (Malta) said that it was not necessary to go to any great expense in setting up a Pasteur Institute in any locality. Thus, in Malta last year, a man was bitten by a rabid dog and the Maltese government at once established a small locale for the inoculation of rabbits after Pasteur's process. This cost annually only between £200 or £300 or at most £400. The rabbits were regularly inoculated, but as yet he did not know that any other cases had arisen in Malta. He was in the Mauritius for some years and there there was a great deal of the disease rabies. In the Island of Bourbon, on the other hand, which belongs to France, no cases of rabies had as yet been seen, as strict quarantine on dogs was obligatory on that island. He was not quite content with the statistics sent from Russia, because in that country there was but little public opinion, and it must be remembered that the laboratories there were carried on by private medical men whose interest it was to make the most of the statistics.

Dr. C. R. Drysdale, of London, said he had first visited the Pasteur Institute in 1886, and had since then visited it every year. He had read also all the literature of the subject, and studied it assiduously, and hence he considered himself able to come to a conclusion. That conclusion was that M. Pasteur had completely proved his assertions, and that he had made the greatest advance in therapeutics which had been made since the days of Dr. Edward Jenner. The statistical proof, although most valuable, was not the proof that had convinced him. Jenner's proof of the importance of vaccination was shown by the fact that he used to vaccinate persons, and then inoculated them in a month or two afterward with smallpox pus, and these cases did not take variola. In the same way M. Pasteur had inoculated forty dogs preventively, and then injected strong virus into their crania, and yet the disease was not produced. It was this experiment that convinced M. Graucher and other Parisian physicians, and made them apply to Pasteur to treat a case of rabies in a boy in 1885. The statistics so admirably given by Dr. Ruffer were a splendid confirmation of the induction made by the greatest of all modern experimenters on virulent diseases, and it required either an amount of indolence of mind or a great amount of obstinacy for anyone of intelligence, who had studied the facts, to reject the conclusions come to in Dr. Ruffer s paper. He answered the question, Ought a person bitten by a rabid dog to put himself under the process discovered by Pasteur? in the following way. Yes! without an hour's delay: because all delay was dangerous, since the incubation of rabies was sometimes under a fortnight. The process was perfectly innocuous even to persons who had no disease, which was found by the great number of gentlemen connected with the Parisian and other similar establishments, who had been preventively inoculated without a minute's ill health or any suffering being caused, except the prick of the injection-needle, which in no case ever caused suppuration, erysipelas, or any mischief whatever. It was absurd to exclaim against treatment which was so pleasant, so rapid, and so perfectly safe. All who had visited the Pasteur Institute would, he was sure, join with him in the admiration he felt for the staff, both medical and lay, of the establishment. The care, incessant watchfulness, patience, and attention shown by M. Pasteur and his friends to the patients was worthy of the warmest eulogiums from all lovers of therapeutics, and he only regretted that the discovery made by Pasteur had been made by a gentleman who was not a member of the profession of medicine. It was time that the audacious falsehood of that envious party in this country, which was composed of anti-vaccinators, social purists, and anti-vivisectionists, should be silenced by the unstinted gratitude of the whole of the medical fraternity of English-speaking nations, and that the name of Pasteur should become enshrined in the hearts of all lovers of human health and happiness.

Dr. Saundby, of Birmingham, said that he was not ready to adopt the enthusiastic tone in which Dr. Drysdale spoke of Pasteur's discoveries. He thought that enthusiasm was dangerous, and that it was well to keep the mind cool and in a critical condition. Twenty years ago

there was a great epidemic of rabies in Birmingham, and no one contracted hydrophobia. This was a remarkable fact, and one which should be accounted for. Pasteur might have done some other thing to treat patients for hydrophobia, and might have been successful. The analogy given by Dr. Drysdale from Jenner's experiments to Pasteur's was not complete; for Jenner had vaccinated before the injection of small-pox pus, whereas Pasteur injected preventively after the virus was already in the system. And this was doubtless also the case when forty dogs were treated by the same treatment. He suspected that there had been far too little open criticism of Pasteur's process. In France, it had become a patriotic thing to sustain Pasteur's name and no effort had been made to judge of it on its real merits. Professor Peter, however, had mentioned the case of a man who had succumbed to paralytic rabies in his hospital and who had been treated in Pasteur's laboratory. That man he, Dr. Peter, considered probably to have taken the disease from the preventive inoculations. Other similar cases had been published where the patients seemed to have died from the effects of rabbit rabies, and not from dog rabies.

Sir William Moore said that, some years ago, a teacher of pathology had published a book to show how poisonous the human saliva was, when injected into animals. As to the cure of rabies by Pasteur's process, it must be remembered that cases had been published when the incubation of the disease had been as long as seven, fourteen, and twenty-one years. He had heard of a case of an incubation of syphilis of twenty-seven months. He knew of a man who had been bitten by a mad dog, and who died hydrophobic six years subsequently. Hydrophobia was not always fatal, for he had published a case where the patient had recovered, and Dr. Bristowe had given another. The result of the statistics put forward by Dr. Ruffer were, therefore, not conclusive, and it was not yet time to pronounce decisively on the Pasteurian process for the prevention of hydrophobia.

Dr. Vaughan Harley said he had studied at the Pasteur Institute for some time, and would remark that the inoculations for rabies were only a part of the work done at the Institute. Other virulent diseases were studied, and he might remark that it seemed not impossible that a vaccine against diphtheria might ere long be discovered at that institute. He could fully corroborate the facts put forward by Dr. Ruffer.

Dr. Torrance said that he might perhaps be permitted to mention what was the treatment of hydrophobia in Syria. In that country, when the disease supervened, a mad priest was asked to spit upon some food, which was administered to the patient, in the hope that like might cure like.

Dr. George Harley, of London, was greatly obliged to Dr. Ruffer for his admirable paper. It was not to be expected that agreement could be arrived at on such difficult subjects, for human brains were so different that what was proof to one mind was not so to another. It was a mistake on Dr. Saundby's part to suppose that Pasteur had remained without criticism in his own country. The very opposite was the case, and the attacks on that great man had been venomous and unscrupulous to the greatest degree, just as had been the case and still was the case in Jenner's country when vaccination was discussed. The value of Pasteur's new ideas concerning virulent diseases was quite enormous; but that great man could not be expected to do everything. He had never personally seen a case of hydrophobia; and it seemed that waves of hydrophobia passed over countries every forty years or so. Forty years ago there was such a wave in England; and Waterton, the Yorkshire traveller, suggested the cure of the disease by means of a poison he had brought from South America with him, viz., ourari. This did not succeed because, in the case of rabies, the virus was not chemical but was a germ. At the time of the famous poisoning by Palmer, he, Dr. Harley, had made many experiments with strychnine on the spinal cord, and had been surprised to find that when he applied the alkaloid to the cord directly no effect ensued, and it was only when he allowed it to get into the blood supplying the cord, that spasms were caused. Hydrophobic virus, however, caused the disease when put in contact with the brain. He wished to say that insanity in the lower animals was not very uncommon, and that it was in no ways connected with rabies, and also that temperature had nothing to do with the production of rabies. In Kant's Arctic voyages, it was mentioned that sixty-five dogs were attacked by rabies and died of it in these cold regions. It was a curious speculation that it was the poisons which the germs produced for themselves which constituted the prevention of rabies, for it was thus the very product of the animals themselves which was used as an antidote for them.

Dr. Eddison, of Leeds, said that it was not generally known that the lower animals may become insane, and, of course, that had nothing in common with rabies. It was not always easy to say that a dog was rabid when it had bitten a person, and the only certain test was the inoculation of rabbits with part of the spinal cord of such a dog. He would like to say that the pain caused by hydrophobia was not so great as that caused by many other diseases, such as cancer or other affections. He had seen cases where the patient had not suffered much before he succumbed. As to the cost of a Pasteur Institute, that was nothing; the real difficulty in this country in establishing such an establishment was the existence of a hateful society which granted to a gamekeeper or a sportsman the right to torture the lower animals in traps, while it forbade any experiment being made on animals for the good of mankind. Forty years ago, in Squire Waterton's days, hydrophobia was common in Yorkshire; but since then there had been but few cases in the Leeds Infirmary. One hundred and fifty sheep were bitten and became rabid, and thus the disease was seen to be a real disease in Yorkshire. He would like to ask whether in the Pasteurian inoculations any slight symptoms of rabies were ever produced. He had been acquainted with Squire Waterton, and felt sure his family would be gratified to have his name so alluded to by Dr. George Harley.

Dr. Rapfer, in reply, said that, as to Sir W. Moore's cases of long incubation of hydrophobia, he could only say that he had taken the greatest pains to get at the truth on this point, and had only found one authentic case where the incubation period of hydrophobia had extended a year. As to Leblanc's statistics, that gentleman, a veterinary surgeon at Rouen, had been most careful in visiting all persons who had been bitten by rabid dogs, and in getting the history of these animals. Dr. Dujardin-Beaumetz had recently made some inquiries concerning rabid patients in Paris, and had ascertained that of three hundred and fifty persons bitten by rabid dogs in 1887, in that city, three hundred and six went to Pasteur's Institute and were treated there; of these three hundred and six, two died. Forty-four persons would not go to be treated by Pasteur, and of these seven died. As to the frequency of rabies in summer and winter, the statistics of the Pasteur Institute gave the lowest number of cases of bites in the month of August, and the highest in February. About one third of the cases were ascertained to be rabid by the inoculation test, and two-thirds by the evidence of veterinary surgeons. As to Malta, he had heard, quite recently, four men had been preventively inoculated in that island by Dr. Kaulana. Russian statistics were quite reliable, for all the medical men practising preventive inoculations in that country had been pupils at the Pasteur Institute. Saliva, when inoculated under the dura mater, often proved fatal; but when it did so it killed in one or two days; whereas, when sterilized rabid cords were injected, the incubation was always the same, *i.e.*, six or seven days. In the former case it was septicæmia that killed. It was quite true that the diagnosis of hydrophobia was sometimes quite obscure. Thus, in a case cited by a French observer, a man was brought to hospital supposed to be

suffering from acute mania; but when the cord was injected under the dura mater of a rabbit, it took rabies. In another case, a man was supposed to have delirium tremens; but he was really hydrophobic, as proved in a similar way after his death. Dr. Peter's case made a great noise, but, when the man died his spinal cord was procured by M. Pasteur and injected beneath the dura mater of a rabbit. The rabbit died after nineteen days, which showed that the man did not die of rabbit rabies, but from the bite of a dog. As to the political question, the way in which M. Pasteur had been treated by many of his own contemporaries in Paris was disgraceful, and humiliating to contemplate. Dr. Peters, in 1887, had published the details of a case of chronic hydrophobia. The patient was said to be in Lille, and accordingly one of M. Pasteur's pupils visited him. The man walked in seven miles from the country to see him, and in short the case was a fabrication, and not one of hydrophobia at all.

Dr. Bateman, of Norwich, read a paper on

THE JURISPRUDENCE OF APHASIA.

He mentioned many cases to show that a patient might be permitted to make a will, which was admitted to probate, although unable to explain himself in speech. Probate was granted in 1870 to the will of a man who had been a deaf-mute. There was also a very remarkable case where a widower, aged sixty-three, about to marry a young lady, was suddenly seized with aphasia. This gentleman showed by signs that he desired to leave £30,000 to the lady he had intended to marry. After death, it was shown by evidence that, on being asked what he wished to leave, he put up the five fingers of his hand, and on being asked if that meant £5,000 he nodded. He held up his hand six times, and was asked whether that meant £30,000. He was then asked if he desired to leave this sum to Miss R——, and he nodded his head. Asked whether this was to be left unreservedly to her, he shook his head. Asked whether the money was to be for her use during her lifetime, he nodded his head. The will was made up and witnessed according to these instructions, and patient affixed his mark. When the case came before the court, the judge said he would have granted probate if the mark of the testator had been put in the right place, but it was made on the body of the deed and not at the end, and this made the document useless. A similar case had occurred in an aphasic gentleman, aged sixty-two, in France, who could not write without copying his handwriting, and whose will was not disputed by the courts. In this case the patient's intellect was excellent, and he could keep up a conversation by means of the deaf-and-dumb alphabet. These were all cases of motor aphasia. When there was sentient aphasia, doubtless the case was more difficult, as the intelligence was thus lessened.

Dr. Eddison, of Leeds, said it was often very difficult to come to a correct opinion as to the amount of intellect remaining in the aphasic patient, and this essay was most useful.

Dr. Drysdale, of London, cited the case of a celebrated civil engineer who had right motor paralysis and aphasia, but who wrote his own checks, copying them from a former signature of his own, and who, for many years, was senior partner of his firm. His partners, however, did all the work. In this case the gentleman retained enough intelligence to play whist with the cards spread out before him, and left a will which was not contested. In a debate on this subject at the Worcester meeting of the British Medical Association, Professor Gairdner had mentioned the case of a Scottish judge affected with aphasia, who had continued in office for some years and sat on the bench while suffering from a form of this malady.

Dr. Rankin, of Kilmarnock, cited the case of a deaf-mute, who had left a will which had not been contested.

## CANADIAN MEDICAL ASSOCIATION.

*Twenty-second Annual Meeting, held at Banff Springs Hotel, Northwest Territory, August 12 and 13, 1889.*

(Reported by our Canadian Correspondent.)

MONDAY, AUGUST 12TH—FIRST DAY.

The selection of Banff Springs as the place of meeting was demonstrated by the large attendance to be an excellent one. Every province of the Dominion was represented, and the arrangements made, both for the comfortable transportation of the members and their accommodation at Banff, were most complete.

The meeting opened with Dr. George Ross, President, in the Chair. He expressed his pleasure at the large and representative attendance, and briefly introduced the President-elect, Dr. H. P. Wright, of Ottawa.

RECEPTION OF DELEGATES.

Drs. Conner and Whittaker, of Cincinnati, Drs. Gibney and Bulkley, of New York, and Dr. Marcy, of Boston, were then introduced to the Association, and received a warm and hearty reception.

AN ADDRESS OF WELCOME.

Dr. Brett, of Banff, on behalf of the Local Committee of Arrangements, presented an address of welcome to the Association, in which every assurance was given that the members present would receive every attention, and that no pains would be spared to make their visit as pleasant as possible; so that the most favorable impression would be carried away regarding the beauty as well as the health-giving properties of the national parks.

PRESIDENT'S ADDRESS.

Dr. H. P. Wright then delivered the President's annual address. His first reference was to the loss sustained by the Association during the past year by the death of Dr. R. P. Howard, of Montreal, one of the first presidents of the Association, and a gentleman whose valuable contributions to past meetings were always so highly appreciated. The importance of establishing a National Board of Health for the Dominion was then dwelt upon, and the good results that might be expected to arise from such an organization were fully commented upon. There were many reasons for congratulation on the advance made in the educational interests of the profession, as might be seen in the raising of the standard of the preliminary examinations required before entering upon the study of medicine, and in the improvements made in recent years in the methods of instruction now carried out in Canadian medical institutions. In regard to the matter of reciprocity of registration between the several provinces of the Dominion and the British boards, a question which caused considerable discussion at the last annual meeting, he said, that through the efforts of the provincial board in the Province of Quebec, reciprocity of medical registration had been secured between that province and the English boards, and he trusted that before long the same satisfactory arrangements would be made by the other provincial boards. The question of Canadian climatology, Dr. Wright thought, might be considered a favorable theme for the consideration of the Association, meeting as it did this year in what was considered by many the most healthful portion of the Dominion. The aseptic nature of the atmosphere in the northwest territories was certainly remarkable, and the virtues of the hot springs of the National Park, particularly in the treatment of rheumatism and syphilis, had already been successfuly established. The early formation of medical boards in these western provinces had already proven of advantage to the public and the profession, and would no doubt afford protection from quacks and charlatans. The address, which was an able review of the present condition and scientific needs of medicine in the Dominion, closed with an extended and able reference to the influence of bacilli in the propagation of disease, and drew attention to the liability of certain diseases, such

as tuberculosis, being communicated from animals to man. Before taking his seat the President expressed the opinion that the present meeting would be highly successful, and that holding the sessions in this western portion of the Dominion would create fresh interest in the welfare and prosperity of the Association.

The meeting then went into executive work, after which it was resolved to adjourn.

---

TUESDAY, AUGUST 13TH—SECOND DAY.

The President, DR. WRIGHT, of Ottawa, took the chair and called for the reading of papers, and expressed the wish that the visiting delegates would feel at perfect liberty to engage in the discussions.

DR. ADAM WRIGHT, of Toronto, presented a paper entitled

HÆMATOMA OF THE VULVA AND VAGINA,

a pathological condition arising from pressure on blood-vessels during pregnancy. He related the history of several cases in which treatment had been successful by free incision.

DR. ROSS, of Toronto, and DR. HOWARD, of Truro, N. S., spoke of the frequency with which such cases are apt to occur, and the importance of their early recognition.

DR. MARCY, of Boston, related the history of a case of thrombus of the vulva, in which he had advised premature delivery. The patient, who was pregnant with twins, would not consent, and went on to full term. Death followed the third day after delivery. The autopsy showed that degeneration of the kidney existed.

DR. RODDECK, of Montreal, favored leaving these tumors alone, unless the growth became large and proved an obstruction, and in such a case he agreed with Dr. Wright in laying them open with the knife.

DR. TRENHOLM, of Montreal, had experience in one case in which he had used the shoemaker stitch, and thus cut off all blood-supply to the tumor. The results had been very gratifying.

Dr. Sloan, of Blyth, and others continued the discussion.

DR. KENNEDY, of Fort McLeod, read a paper on

THE CLIMATE OF SOUTH ALBERTA,

with special reference to its advantages for patients with pulmonary complaints. He gave an interesting description of the soil and the different atmospheric changes common to that territory. In eleven years' practice he had known only four cases of pneumonia, and phthisis was indeed a rare disease. Many who came to Alberta with incipient phthisis recovered. The atmosphere was certainly peculiarly aseptic, and the rapid healing of wounds was a wonder to many. They were not altogether free from disease in the territory, for they were often troubled with a mild form of fever pronounced by some to be typhoid, and by others to be entirely of malarial origin. The climatic influences of Alberta were certainly most favorable to health, and he ventured to predict that when the salubrious climate of the territory became well known, and its marked suitability as a health-resort were understood by the Canadian people, many would avail themselves of its advantages.

DR. OLDWRIGHT, of Toronto, expressed the hope that the Dominion Government would establish meteorological stations, from which valuable observations might be made in Alberta. This, he thought, would furnish information much to be desired regarding the climate of the territory.

DR. MCINNIS, of Edmonton, spoke of the abnormally high temperatures often met with in Alberta. He had frequently noticed a temperature of 108° F. followed by recovery. What would be considered an alarmingly high temperature in the east was commonly met with in this western territory. There was also marked absence of the typical features as seen in intermittent fever in the east. He corroborated the evidence of Dr. Kennedy regarding the great immunity enjoyed by Alberta from pulmonary diseases.

DR. HENDERSON, of St. Paul, Minn., had had considerable experience as a railway surgeon in the early history of Alberta, and had noted the frequency with which high temperatures were recorded.

DR. BENTLEY, of New Westminster, B. C., had found no cases of intermittent fever which had arisen in British Columbia. There was considerable difference of opinion among medical men, at the Pacific coast, as to the real nature of the mild form of fever they often had to deal with. While some pronounced it typhoid, others ascribed to it a malarial origin and called it typho-malarial fever.

DR. WHITTAKER, of Cincinnati, deprecated the use of the term typho-malarial, and hoped to be able to return and inform his confrères in the east that he had attended its funeral on the top of the Rocky Mountains. Pathological research had, he thought, established the fact that examination of the blood would disclose whether a typhoid condition was present or not. Regarding the immunity from phthisis in Alberta, he considered this would strengthen the contention that upon purity of the air more than upon anything else depended the successful treatment of that disease. To the high altitude of the territory might be ascribed the more rapid circulation and decreased respiration, and these circumstances, with the aseptic atmosphere, might account for the freedom so happily enjoyed from pulmonary diseases. He combated the idea of the supposed hereditary nature of phthisis, and was convinced that small apartments and neglect of hygienic measures to secure pure air were great factors in the cause of that disease.

Dr. Henderson, of Kingston; Dr. McLennan, of Trenton, and Dr. Praiger, of Nanaimo, B. C., continued the discussion, and expressed pleasure that the claims of Alberta as a territory enjoying such freedom from pulmonary diseases had been so well presented.

DR. GIBNEY, of New York, opened an interesting discussion on

THE TREATMENT OF HIP-JOINT DISEASE.

The term hip-joint disease was, he thought, somewhat misleading. He looked upon it as a disease almost entirely of tubercular origin, and taking this view, we are greatly assisted in our management of these cases. Absolute and complete immobility of the affected joint was, he considered, the foundation for all treatment. An abundant supply of pure air, with good, wholesome nourishment, were most important factors in the treatment. He had not had much satisfaction in the use of any of the splints devised for the treatment of this disease, but thought the perineal crutch useful in some cases. A plaster-of-Paris dressing extending from the free ribs downward, applied sufficiently strong to secure immobility, was necessary. There was no fear of trouble from anchylosis of the joint in these cases. In conclusion he related the different steps to be taken, should operation be found necessary.

DR. CONNER, of Cincinnati, thought, with the previous speaker, that tubercle bacilli were the main cause of hip-joint disease. The joint was found to be a favorite resting-place for bacilli, where it became encapsulated, and either remained dormant or gradually developed, and thus caused extension of the disease. In reference to treatment, if the joint were kept absolutely quiet, nature might take care of the tubercle, and successful or partially successful results would follow. If, however, operative interference became necessary, recourse might be had to (1) freely opening and scraping out the tubercular deposits; (2) exsection of the hip-joint; or (3) amputation of the limb. He had been obliged to favor the latter in severe cases, but considered early diagnosis and prompt treatment, by securing complete immobility of the joint, would often render unnecessary the operations for the cure of this disease. He emphasized the importance of having the patient kept in as completely an aseptic atmosphere as it was possible to secure.

Dr. Strange, of Toronto, related an interesting case of hip-joint disease of traumatic origin. If operation became necessary in cases of a tuberculous nature, he favored opening the joint freely, and removing with the strictest antiseptic measures all tubercular deposits. He believed all such cases should be kept in the open air as much as possible.

Dr. Roddick, of Montreal, favored extension as a valuable addition in treatment of these cases. Careful distinction must be made between the tubercular and non-tubercular forms of the disease. The successful treatment was very often dependent on the early recognition of the disease.

The discussion was continued by Drs. Oldwright and Cameron, of Toronto; Shepherd, of Montreal, and Praiger, of Nanaimo, B. C.

Dr. Buller, of Montreal, read a paper on

PREVENTIVE DEAFNESS.

He first produced statistics showing the prevalence of deafness, and dwelt on the importance of early recognizing and promptly treating any symptom of deafness in childhood. The cause at first might be trivial, and its early discovery and removal was of the utmost importance. The oft-repeated fallacies that it was dangerous to check a discharge from the ear, and that a deaf child often recovered without any treatment, were often heard from the laity, but medical men should discourage and promptly refute such opinions. Earache, instead of being looked upon as a trivial matter, should call for a careful examination and diagnosis. Negligence, in not attending to what might seem but a slight defect in the hearing of a child, often led to serious trouble.

Dr. Reeve, of Toronto, said early attention to the walls of the pharynx, looking particularly for a hypertrophied condition, would in many cases remove what might ultimately lead to deafness in children.

Dr. Grassitt, of Toronto, presented a paper on

COLLES' FRACTURE.

After briefly describing the triple displacement of the lower fragment of the radius and the consequent difficulty in getting the displaced portions exactly reduced to their proper relations, he proceeded to discuss the different methods of treatment. In treatment of this fracture there must be no timidity on the part of the surgeon, who must carefully manipulate until reduction is secured. After that it mattered but little what form of splint was used, as long as the displaced fragments were kept exactly in place.

Dr. Roddick, of Montreal, thought care should be taken to break up the impactions and carefully readjust the parts. He favored using an anæsthetic in all such cases. In regard to splints, he favored an anterior splint with a ball in the palm of the hand.

Dr. Cameron, of Toronto, spoke highly in favor of Moore's dressing in Colles' fracture.

Drs. Sloan, of Blyth; McLennan, of Trenton; Geikie, of Toronto; Bust, of Paris; Smith, of Seaforth; Reddell, of Crystal City, and Stockwell, of Port Huron, Mich., continued the discussion.

Dr. James Ross, of Toronto, read the history of an interesting case of

EMPYEMA,

treated by free incisions.

Dr. James Stewart, of Montreal, presented a paper on

SULPHONAL,

giving the histories of fifty-two cases in which that drug had been administered as a hypnotic. When severe pain was present he found the drug useless; but in those cases where there was sleeplessness without pain it was highly useful. In those neurotic cases where the morphia or chloral habit had been developed, it was the means of securing beneficial sleep when given in twenty-grain doses. There was, he believed, no fear of the habit being established, as in the commonly used narcotics. Sulphonal produces no disagreeable secondary symptoms, nor any unfavorable effects on the heart and circulation. Its action was by giving rest to the cells of the cerebral cortex and thereby causing sleep. The dose was from fifteen to fifty grains, the ordinary dose being twenty grains. It was somewhat slow in its action, so that it was necessary to administer the drug early in the evening to secure a night's sleep. In some cases he had noticed six hours would elapse before sleep was produced. Large doses had been known to produce ataxic symptoms, but these were generally mild in character and soon passed away.

Dr. Whittaker, of Cincinnati, said that his experience in the use of sulphonal confirmed all that Dr. Stewart had related in its favor. As an agent to procure sleep he considered it was a most valuable remedy. He had used it in the largest doses, and had never seen any danger, nor the least symptoms of danger from its use. There were persons who could not sleep while travelling on a train or steamer. Such persons might have a good night's rest free from any objectionable after-effects by taking early in the evening twenty grains of sulphonal. He believed that it was of no value as an anodyne, but given in those cases requiring simply a hypnotic it was reliable in its action, and as such it was a new and valuable remedy.

Dr. Reeve, of Toronto, read a paper on

PAINFUL AFFECTIONS OF THE EYE AND EAR.

Dr. Whittaker, of Cincinnati, presented a paper on

VARICELLA,

reviewing some of the peculiarities sometimes associated with this disease.

Dr. George Ross, of Montreal; Dr. Bulkley, of New York, and others continued the discussion of the subject.

Dr. F. J. Shepherd, of Montreal, read a paper on

NEPHRO-LITHOTOMY,

giving a report of an interesting case in which the right kidney had been incised for calculus, with success.

Dr. Conner, of Cincinnati, discussed the subject at length, giving interesting reports of cases, and affirming that there should be no hesitation in cutting down upon a kidney where the existence of calculus was suspected.

Dr. Dupuis, of Kingston, and others continued the discussion.

Dr. L. Duncan Bulkley, of New York, presented a paper on

THE EARLY RECOGNITION AND TREATMENT OF EPITHELIOMA.

He first made reference to the importance of the early recognition of epithelioma, a condition which might often escape notice for considerable time. There were three methods by which we might seek to eradicate the disease: 1, excision; 2, erasure by curette; and, 3, destruction by caustic agents. After reviewing all the methods of treatment, Dr. Bulkley gave evidence from his own experience, of the success obtained from the application of Marsden's paste, consisting of arsenic, two parts, to one part of gum acacia. This, applied for a period of twelve hours, in the early history of a case, had often served in his hands to destroy the epithelial cells. He deprecated the use of nitrate of silver, and other similar agents likely to irritate, and thereby encourage the growth, but thought that in the use of the arsenical paste we had a valuable means of treating epithelioma.

Drs. Stewart, of Truro, N. S.; Chamberlain, of Morrisburg, and others continued the discussion.

The following papers were read and fully discussed:

"The Radical Treatment of Hernia," by Dr. Cameron, of Toronto; "A Résumé of a Few Surgical Cases," by Dr. Praiger, of Nanaimo, B. C.; "Some Improvements in Medical and Surgical Instruments," by Dr. Dupuis, of Kingston.

ELECTION OF OFFICERS.

The report of the Nominating Committee was presented, and the following officers were unanimously elected:

*President*—Dr. James Ross, Toronto; *Vice-Presidents*—For Ontario, Dr. Bruce Smith, Seaforth; for Quebec, Dr. La Chapelle, Montreal; for Nova Scotia, Dr. Johnston, Sydney Mines; for New Brunswick, Dr. Holden, St. Johns; for Prince Edward Island, Dr. McLeod, Charlottetown; for Manitoba, Dr. Spencer, Brandon; for Northwest Territories, Dr. Brett, Banff; for British Columbia, Dr. Evarts, Nanaimo; *General Secretary*—Dr. James Bell, Montreal; *Treasurer*—Dr. W. H. B. Aikins, Toronto.

Several resolutions were passed relative to the importance of establishing meteorological stations in the Northwest Territories, and of the desirability of every effort being made to furnish the fullest information regarding the climate and other advantages of the territory of Alberta as a health-resort.

It was also resolved to continue every effort to induce all local medical societies throughout the Dominion to incorporate with the Dominion Association, and maintain friendly relations between the parent body and the different provincial and county societies.

The usual motions of thanks were then passed, and the twenty-second annual meeting of the Canadian Medical Association was brought to a close.

## Correspondence.

### SOME OF THE DANGERS THAT THREATEN INVALIDS WHO TRAVEL IN RAIL CARS.

To the Editor of The Medical Record.

SIR: For several years I have made long journeys by rail in search of climatic conditions favorable to a renewal of health. Through the South to Florida, west as far as California and the Pacific Islands; in fact, to all the well-known resorts of the country. I have travelled principally by rail. I might call your attention to many things in the running of the trains by day and night, car construction, wayside dining conveniences, and in which at slight expense a great improvement for the benefit of the travelling public, and especially of invalids, might be made. But none more important, or that calls for more immediate action by the companies furnishing parlor or sleeping-cars, is there than that of improvement in the closet conveniences. I have found in many, and at all seasons of the year, that the closet opens directly to the open air beneath, and the motion of the car compels a strong current upward and inward. In any season of the year this must be, and is, extremely unpleasant to every traveller, and especially so, if not dangerous, to invalids on a journey, whether of one or six days; but in cold or wintry weather the exposure to the frosty current is extremely dangerous to those affected by some, if not all, diseases. On a few cars I have found ample provision assuring immunity from these dangerous air-currents, but in the majority of cases, and especially on the older Eastern roads (using old cars, etc.), the arrangements are of the most primitive character. The few new cars occasionally met with on these roads, though frequently advertised, do not seem to have been constructed with much reference to the comfort of long-distance travellers. The medical profession should take this matter in hand, and disregarding advertisements (and the few new cars for special exhibition), ascertain from actual inspection by a reliable person, what roads reaching winter or summer health-resorts provide cars convenient and safe for invalids, and not hesitate to advise their patients in this very important regard. In fact, the result of such an inquiry ought to be made as public as possible.

MISSOURI.

SARATOGA, September 10, 1889.

### THE PROPER TEACHING OF ANATOMY.

To the Editor of The Medical Record.

SIR: I have just read your editorial on "The History and Cost of the Didactic Lecture," in THE MEDICAL RECORD of July 27th, and heartily agree with much that is said concerning the waste of time in hearing tiresome, badly delivered lectures, containing nothing that cannot be readily and more agreeably found in current text-books. I heartily approve of the principle that students should be allowed to attend the lectures of any man who gives interesting instruction, and not be forced to listen to one teacher because he happens to be the holder of a certain collegiate chair. Nothing would so much as this stimulate our college professors to increased activity in their own sphere. A man, sure of his fees and certain of a compelled attendance, has little stimulus to scientific enthusiasm and improved methods of instruction.

I cannot, however, avoid criticising your remarks regarding anatomy, which are contained in the following paragraph:

"No wonder, then, that many didactic lectures are poorly attended. The student knows that he can find all the information in text-books, and sees no reason why he should listen to another's reading of the same. *Particularly is this true of a subject like anatomy. It is not a fault of any one man or any one institution. It is a universal one.*"

I have italicized the words because I am so sure that they are deductions from wrong premises. The reason that anatomy is considered a dry and wearisome study is because its so-called teachers do not teach it in an interesting way. In other words, the fault lies with the man and the institution. The chair is often, perhaps usually, given to a man who does not practise medicine or surgery. As well might materia medica and therapeutics be given to a man who never wrote a prescription or felt a pulse. Let anatomy be taught by those whose daily work brings them in contact with injuries, deformities, and anatomical landmarks, let it be portrayed on the living models as in our schools of painting and sculpture, let the student see that the men who teach anatomy make their professional living by knowing surgical anatomy, let the electrical current be employed to illustrate the function of individual muscles and to elucidate the complicated movements of the joints, and then no student will think he can find all the anatomy he wants in text-books.

If, however, the teaching of anatomy, the foundation-stone of all medicine, is intrusted to life-insurance examiners, to retired practitioners, or to peripatetic scholars who never enter a sick-room, it is no wonder that it becomes a mere catalogue of human tissues, and far less interesting to the hard-worked student than the columns of Dunglison's Dictionary. Anatomy *can* be taught so as to interest every earnest medical student. In my student days it was so taught in this city of Philadelphia by at least one man, and, as he still lives, it can be so taught at this day by him; possibly also by those who enjoyed his anatomical lectures in the Philadelphia School of Anatomy. Don't blame the science, I beg of you; blame its poor exponents.

Respectfully,

JOHN B. ROBERTS, M.D.

PHILADELPHIA, PA.

---

NITRATE OF SILVER IN HYDROCELE.—A number of French surgeons have recently returned to the old method of treating hydrocele, called by some Defer's method, and express a decided preference for it over the treament by injections of iodine. After drawing off the fluid, a probe, on the point of which some nitrate of silver has been fused, is passed through the cannula, and the remedy is thoroughly applied to the inner surface of the tunica vaginalis. The reaction following is similar to that after the use of iodine, and the subsequent course is also the same. The advantages of the method are that it is more simple and easy of execution and is also cleaner.

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 15 to September 21, 1889.*

SMITH, ANDREW K., Colonel and Surgeon. By direction of the acting Secretary of War, leave of absence for fourteen days, on surgeon's certificate of disability, is granted. Par. 1, S. O. 214, A. G. O., September 14, 1889.

STERNBERG, GEORGE M., Major and Surgeon. By direction of the acting Secretary of War, having completed the duties assigned him in War Department order dated February 4, 1889, S. O. 30, February 5th, A. G. O., is reassigned to duty as attending surgeon and examiner of recruits at Baltimore, Md. Par. 12, S. O. 218, A. G. O., September 19, 1889.

*Official List of Changes in the Medical Corps of the United States Navy for the week ending September 21, 1889.*

BEARDSLEY, G. S., Medical Inspector. Granted six months' leave with permission to go abroad.

RUTH, M. L., Surgeon. Order granting furlough revoked and placed on waiting orders.

Medical Director HUDSON, Medical Inspector WOODS, and Surgeon DICKINSON, will continue as president and members of an Examining Board for examination of applicants for the position of Assistant Surgeons in the Navy, at San Francisco, Cal, until June 30, 1890.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 21, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 41 | 18 |
| Scarlet fever | 24 | 3 |
| Cerebro-spinal meningitis | 0 | 0 |
| Measles | 7 | 0 |
| Diphtheria | 55 | 10 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

THE BREEDING OF SINNERS.—The French Government hopes, apparently, by promoting marriages between male and female convicts, to bring back these stray sheep into the fold of morality and good conduct. Arrangements have accordingly been made to facilitate these unions, but physiologists and pathologists must feel sundry qualms as to the expediency of such a course. The physical and moral degradation of many of these social waifs is distinctly hereditary, and a careful moral training (which is not provided for) would, at the most, only modify the tendencies which have brought them within the clutches of the criminal law. The son of a poet is not of necessity a poet, but the offspring of a bawd or an assassin is extremely likely to develop the same proclivities. If even one of the parties to the transaction were worthy of respect some regeneration might be hoped for, but the association of two hopelessly abandoned bodies and souls is not calculated to improve matters in any respect whatever.—*The Hospital Gazette.*

TOO MANY DOCTORS EVERYWHERE.—As we have had occasion to note several times, it is not in America alone that complaint is made of an overcrowded state of the medical profession. The same condition prevails in England and France and Germany, and, indeed, all over the continent of Europe, except in the country districts of Russia. In the latter there is great need of physicians, but no money to pay them with. In an article in *Le Concours Médical* Dr. Grellety draws a dismal picture of the struggle for bare sustenance among the physicians of Paris. There are plenty of doctors, he says, with hospital experience, who do not make enough to pay their rent, and others who live on such short commons that a cutlet for dinner marks the highest feast-days, and even beans are regarded as a luxury that is attainable only now and then. He says that it was once proposed to institute at the "École des Beaux-Arts" a course for the discouragement of artists; the object of such a course being to demonstrate the cruelty of inflicting upon the community an exhibition of such daubs as most so-called artists now turn out. And he thinks that a similar course as a preliminary to medical studies would serve a most excellent purpose. The intending student could learn of the hardships of the average physician's life, the difficulty which he would have in making both ends meet, and his poor chance of ever making a success in life as regards either reputation or money.

A SIMPLE REMEDY FOR HICCOUGH.—Dr. Loebl reports, in the *Allgemeine Wiener Medizinische Zeitung*, No. 32, 1889, the case of a man, aged fifty-four, who suffered for five days and nights from a most obstinate hiccough. After trying all the ordinary measures without avail, he fell back upon a household remedy as a last resort, and ordered a teaspoonful of pulverized sugar wet with an equal volume of wine vinegar, to be taken at one dose. The hiccough stopped immediately, and did not return for six hours, and then ceased again upon a second dose of the remedy.

DANGERS OF CARBOLIC ACID.—Professor Billroth has called attention to the danger residing in the popular use of carbolic acid as an application to wounds and injuries of all sorts. He says he has seen four cases in as many months of insignificant injuries of the fingers to which carbolic acid was freely applied with the result of gangrene of the parts. He urges physicians to warn their patients against this drug, and recommends lead-water as the safest and most effectual application to slight wounds.

FEMALE PHYSICIANS IN LONDON.—England is said to have but seventy-three female physicians, of whom the leading one is Dr. Scharlieb. She was the first woman to receive a medical diploma from the University of London. After residing in India for a time she returned to London where she soon acquired a very large practice. Dr. Garett-Anderson, a Paris diplomée, is another of the leading female practitioners of London. She was instrumental in establishing the woman's hospital in London, and is dean of the school attached to the hospital, and also holds the chair of medicine. This hospital is managed entirely by women, the apothecary and attending physicians being women, the consultants only being of the opposite sex.—London correspondent of the *Semaine Médicale.*

ELEPHANTIASIS.—Dr. T. J. Bennett reports, in the *Texas Medical Journal*, for August, 1889, the case of a negress, fifty years of age, with elephantiasis of nearly three-fourths of the entire body. He gives the following measurements of the patient: Height, 5 feet 3 inches; weight, 440 pounds; ankle, 26½ inches in circumference; knee, 31½ inches; thigh, 46 inches; abdomen, 6 feet; largest part, 6 feet 6½ inches.

MISS KATE COREY, M.D., a graduate of the University of Michigan, has recently been admitted to honorary membership in the Indiana Medical Society, the first time, it is stated, this recognition has been extended there to a woman. Dr. Corey has been for four years the principal surgeon in charge of a hospital at Foochow, China, and has, it was stated in the convention, performed almost every surgical operation known.—*Medical and Surgical Reporter.*

## Original Articles.

### THE INFLUENCE AND WORK OF THE ACADEMY.

BEING AN ADDRESS DELIVERED AT THE LAYING OF THE CORNER-STONE OF THE NEW YORK ACADEMY OF MEDICINE, OCTOBER 2, 1889.

BY A. JACOBI, M.D.,

EX-PRESIDENT OF THE ACADEMY.

THE New York Academy of Medicine has called upon the profession and the public alike to assist it in this ceremony of laying a corner-stone. Where we are now standing there will be the home of the Academy, we believe, for generations to come. If we be mistaken, if this large building will be too small before long, it will be the pleasant duty of our successors to provide for their wants. That this may become necessary is possible, for the Academy has experienced a development rapid beyond expectation. Forty-three years ago it was founded, dozens of years it held its meetings in hired quarters, ten years ago it occupied its own building, No. 12 West Thirty-first Street, to-day we are preparing accommodations such as the profession of New York, or any other city of the country, has never possessed. Meanwhile, however, the spirit and the aims of the Academy have remained intact. Among these aims are the cultivation of the science of medicine and the promotion of public health.

In the words of a circular published nearly two years ago in behalf of our building fund, "these purposes are accomplished by lectures and discussions in the stated meetings of the Academy and its numerous sections; by maintaining reading-rooms which furnish nearly all the medical journals of the world, and by collecting a library containing about sixty thousand books and pamphlets, which are free both to the medical profession and the public." The number of its fellows is nearly six hundred. They have been selected from among those who have practised medicine in New York City or its vicinity three or more years. Some time ago fellowship has been extended to those residing in the State.

In its composition the Academy participates in many of the peculiar features of our political organization, which means to benefit all through the co-operation, if not of all, still of the best. In Europe an Academy of Medicine means a small body comprising a few select men only, appointed by the body itself when there is a vacancy, or by the political rulers. Thus the Academies form an aristocracy of the mind parallel to the aristocracy of birth, with all its exclusiveness and real or assumed superiority. They are representative bodies only in this that the best minds and most scientific workers are expected or believed to fill the seats.

The New York Academy of Medicine, however, is a democratic institution. It is not limited in numbers—on the contrary, it is desirable that the many respectable physicians should gather round its flag. Like our political commonwealth, it must look for its development and success in the co-operation of the competent and cultured masses. Like the Union, it is a voluntary confederation of peers who make their own laws and obey them because they are of their own making.

The members have common interests, both scientific and professional. Since its foundation, with the changes for good and bad appertaining to everything organic, the Academy has prospered constantly, in spite of, or as I am more inclined to say, in consequence of its very constitution as an independent and democratic body. In the words of the same circular alluded to before, "the Academy is not connected with any school or college. It is self-supporting and is carried on in the interest of the whole profession. There are no fees nor emoluments of a private or individual nature. It is not supported nor subsidized by the State or municipality." Whatever has been accomplished by it—its scientific labors, most of which are laid down it its "Bulletins" and "Transactions," and in the medical journals of the country; the hall in West Thirty-first Street; the library and reading-rooms in the upper stories; the wealth of books and journals at the disposal of those eager to learn, and so numerous that they alone compelled us to look for more appropriate quarters—all of that has been created, with few exceptions, by the exertions and pecuniary sacrifices of the medical men themselves.

All classes of these are represented in the Academy. It shows you the choice of those who are interested and active in the promotion of medical science and art; those who have earned an international reputation; those who have deserved well of the community by a life filled with services rendered to the public; and those who look forward for the fulfilling of their dreams and the reaching of their aims through coming years of honest labor spent on theoretical study and practical work. In this co-operation of the old and young, the illustrious and those yet unknown, but promising or anxious to earn renown, the mature and the maturing, you have one of the features of a unity of the profession.

Another feature of unity which, moreover, ties the profession indissolubly to the community at large, is the labor performed in the service of one and all. It is in these labors and their results that the community at large ought to take a deep interest. Modern medicine is probably the greatest benefactor of mankind. The more medicine has been founded on the study of the exact sciences, chemistry, physics, and physiology with mathematics, the more has its field of usefulness enlarged. The more theoretical it appeared to become, the more did it develop practical usefulness and dignity. Indeed, the dignity of a science or study rises with its ability of being utilized in the service of mankind. Now, the promotion of medical science and art does not mean only the improvement in diagnosis and in the administration of drugs and remedies, but the discovery of the best means of placing the human being in the best possible condition. The labor of the physician is not exhausted by carrying you through a severe case of illness, he renders you the greater service, less remunerative to him though, of preventing you from falling sick.

The peculiar relations of the individual physician to his patient or the family intrusted to his care, are widened in the relations of the profession to the public. Great epidemics take the place of a single case, the protection of a community that of the guarding a person, the hygiene of schools that of a dwelling, the sanitation of a large city that of inspecting a suspicious trap or sewer in a private domicile. The more in your health department the medical element will predominate over the military and political, the more actual benefit will the people derive from it. The hygiene of the whole population, the superinten-

dence of public buildings in which many people old or young are gathered, public hospitals, quarantine stations, the questions of physical and mental elevation, of legal responsibility, of the State care of the insane, they all belong to the domain of the profession. This is not theory only. No grave question of the kind has come up without the gratuitous and spontaneous aid of medical men. The Health Board of the city has long appreciated that. The Academy has furnished a consulting board to all the health department's hospitals. A committee of the Academy was intrusted with the inquiry into, and the report on, the condition of Quarantine. It is to its report that the first appropriation for the rebuilding of the Quarantine Station was due, and to its recommendations that improvements are being carried out at the present time. In this way the medical profession excludes epidemics, and guards both the physical health and the economic interests of the city. Imagine the pecuniary loss to the city if the cholera and the yellow fever scare of a year or two years ago had not been prevented by the profession, as indeed it was. A week's panic would have been a pecuniary calamity amounting to the loss of a good many millions.

These are but a few examples of the value of medical services, both paid and unpaid ones, to the public. The health of the city is the foundation of its prosperity. Let epidemics prevail, and not only will your children die, your families be decimated, and the graveyards be filled with places where flowers and tears mingle, but your commerce will be drawn to other ports. It is due to increased knowledge and activity on the part of the profession, both official and unofficial, that in spite of the unchanged severity of the epidemics and the rapidly increasing population of the city, the number of cases of diphtheria shows an absolute diminution.

Such among many are the services of the profession, not to speak of the gratuitous daily work of hundreds of medical men in the hospitals and dispensaries. Nobody can count or calculate, but everybody can appreciate how many lives are preserved, how many millions are saved for the poor and rich alike. From that point of view, a whole-souled, generous woman presented to the Academy $25,000, in recognition of the services to the public on the part of the profession, and in accordance with the esteem her husband held the profession in while he was alive. To this consideration we owe the bequest of $70,000, coming to us under the will of Mrs. Alexander Hosack, who had spent a large part of her valuable life with illustrious examples of professional worth. It is the same thought that induced men and women with means, intelligence, and public spirit to make donations of five, two, or one thousand dollars. All we require now is $50,000 to complete this building. There must be many who have that sum or a part of it to spare in the interest of the profession; perhaps to commemorate the name of a dear one who has passed away, or to imprint his or her name—and a legitimate ambition it is—on one of the halls of the new building, or to perpetuate the memory of one who has been saved from a premature grave by the endeavors of one of those who are now striving to erect a home for the most practical and beneficent of all sciences and arts.

It is a home we want, more than merely a house. To make the house of the medical profession a home, it requires a library. This is to the profession what a tool is to the mechanic, an engine to the engineer, a telescope to the astronomer. A complete library represents the thoughts, experience, genius, and discoveries both of all previous centuries and the present time. All of these treasures must be accessible to the profession whose knowledge and skill is to be the safeguard of the public's best interests. To accomplish that end the whole medical literature of all countries must contribute. New York has never been satisfied with anything that is second class; it cannot afford to trust itself to a profession without the first order of learning and erudition.

Why do we insist upon physicians being erudite? Do I ask why do you apply to a particular watchmaker, an engineer, an architect, a milliner? You select him because you believe or know him to be well informed or skilful. And the physician? His practice is the application of knowledge acquired by hard brain work spent on all the learning and practice which have been evolved out of the labor and efforts of thirty centuries. A learned doctor may happen to be an unsuccessful practitioner for more reasons than one; but among those reasons erudition is not. An uninformed man is never a good practitioner; under equal circumstances, the more learned man is the better man in practice. Practice and learning do not exclude each other; on the contrary, the former depends on the latter. It ought not to suffice for your selection of a doctor that you met him at a bar, or a ball, or at a church meeting, or at whist, in a concert, or on a hotel piazza, or that he be well dressed, pleasant, and tells you he is your "friend;" all these are fine opportunities and agreeable social and personal qualities which may also be considered when you are credibly informed that he burns midnight oil over medical literature and that his professional brethren speak well of his abilities and achievements. And as far as medical friendships are concerned your best friend is he who knows best how to protect you and your children and your parents from disease, and to cure them when they are sick.

The erudition we claim for the profession demands a large library of constant growth. A fund of $100,000 will enable us to keep abreast with any similar institution. The library of the Surgeon-General's office in Washington, which contains at present seventy thousand volumes and one hundred and thirty thousand pamphlets, is the result of industrious and systematic collections. It is not much over twenty years old, but it is the richest and most complete medical library in the world. Still its annual appropriations for the purchase of books have seldom exceeded five thousand dollars. Thus a fund of $100,000 will enable us to procure nearly everything medical that appears in any land. Of that sum we have only $10,000. One-half of that sum was set aside by the Academy, the other half is a donation separately administered in perpetual honor of a departed one. Such special funds, or additions to our general library fund, are urgently requested. The citizens of New York have developed a metropolis of large size and commercial power; they can well afford to tax themselves in the interest of medical science, than which there is none more cosmopolitan and humanitarian.

But it is not the medical profession only which will be directly benefited by the endowment of a large and complete library. The intimate relations of the medical and legal professions are such that much of what we require is found in law books, and the lawyer has to look for much of his information in medical literature. Indeed, forensic medicine, which originated in law, has its main representatives in medicine. In both the names of Thenck and Tloucquet, Farr and Duncan, and our own Beck, and many others of more modern times, are household words. Moreover our library is a public one, free to the profession and the public. Now, there is a class of literature which in a free and public library like ours ought to be well represented. Laymen intending to avail themselves of it expect to find mental food adapted to their comprehension and taste. That sort of literature is by no means scarce. Much of it is of fair quality, some of it surpassingly good. Books on anatomical and physiological topics, those on subjects connected with natural history, hygiene, and statistics, will always be found interesting and instructive. They ought to be well represented in our library, for they cannot be found in large numbers in the public and circulating libraries. Indeed the frequenters of the latter differ much from the class of readers consulting ours.

The additional knowledge acquired in this manner will not only improve a man's ability to protect himself and his family, he will also facilitate the work of his doctor.

A person who has filled his mind with comprehensible ideas and sound facts will no longer study quack advertisements. He who has learned something about the functions of his body and been taught to consider the correlation of causes and effects, can appreciate a disease to be the result of either a preventable or an unavoidable cause, and recognize that whatever disease was not the result of faith cannot be cured by faith, not even by faith in panaceas. The business of the quack may thus cease, the nostrum-mixers may suffer, but individual and public health will be the gainers. There is less sickness in a man who has some knowledge of his body and its requirements; and when he falls sick he expects relief from natural and intelligible sources only. That man is a better patient, more accessible to reasoning, more obedient to the rules imposed in the interest of recovery. If he knows enough to recognize the superiority or inferiority of his physician, so much the better. To-day most people have not a sufficient knowledge to guide them in their selection; there are many who are so little informed that they do not so much as care. If in a matter ever so trifling a medical man is called as a witness before a court of justice, the first question he is asked refers to his membership in a medical society The uninformed public, however, often select their doctor for reasons known to nobody, least, perhaps, to themselves. All this would be changed if a small part of what is the basis of a physician's thinking and knowing were made accessible and intelligible to every man and woman. A library like that which we intend to establish, is destined not only to supply the professional man, but furnish healthy mental food to all those who are thirsty for knowledge. Those who have means to spare in the interest of public education, hygiene, and health, cannot possibly apply them better than by providing for a library fund sufficient for the gradual accumulation, from year to year, under the supervision of experts, of all the good popular literature on the subjects of anatomy, physiology, hygiene, dietetics, and statistics.

May all this become true! We are preparing this edifice to be the head-centre of medical study in the city, an example to the profession of the country, and a resort for the brethren who come to us from near or distant parts. This building when completed will be an ornament to the metropolis. What is still more important is that we mean it to become, and feel assured that it will be, an additional element of intellectual and ethical power, and in its results a blessing to the commonwealth.

## ON THE BACTERIOLOGICAL TEST OF DRINKING-WATER.[1]

By EDWARD K. DUNHAM, M.D.,
NEW YORK.

Our interest in the bacteriological examination of water rests upon the belief that by its aid we may detect the presence, in a sample of water, of bacteria injurious to health; but still more upon the well-founded hope that, through its assistance, we can, or soon shall be able to, estimate the chances that a given water-supply will, in the future, be contaminated with such bacteria.

It is this power of foreseeing danger which gives the test its greatest value, and it is to that power that I wish particularly to direct attention on this occasion.

In doing so, it may, I fear, be necessary to consider some of the details of the test more minutely than strictly accords with the general character of an address. But it appears as though the principles involved in the test could not be clearly manifest without some reference to the details of which they are in a great measure generalizations.

In the application of this test the greatest difficulty lies in the proper interpretation of the results obtained by the employment of some of the simplest of bacteriological procedures—namely, the isolation and counting of the living bacteria in a given bulk of the sample submitted to study. And, in practice, we find some diversity in the manner of interpreting results on the part of different observers. Some have contented themselves with a statement of the number of living bacteria found in a standard quantity of water, usually one cubic centimetre, and have condemned those samples which contained more than a number previously fixed upon through the examination of waters free from suspicion of injurious contamination.

Other observers have depended for their judgment upon the detection of species of bacteria of recognized pathogenetic character, considering, with justice, the presence of even relatively large numbers of non-pathogenetic bacteria as in itself a practically harmless circumstance.

The criticism to which the first of these two methods is open, is that it is too sweeping in its condemnation of those waters which contain more than a very few bacteria. For the numerical standard of good water must be set at a low figure in order to exclude some waters which are open to question; whereas, undoubtedly, many waters containing large numbers of bacteria are above suspicion.

The second method is open to the serious objection that, in order to give a decisive opinion, it depends upon the finding of species of bacteria which may be present in but small numbers, and which are then very difficult of identification in the presence of a number of other species. Therefore, although its verdict is conclusive when positive, its results can be of no value when negative; and, moreover, a negative result can throw no light upon the chances of a future contamination of the water supply with injurious bacteria.

There is a third method of interpretation which has a much higher aim than either of the two already mentioned, and which is capable of becoming more exact in proportion to the advances made in our knowledge of the part bacteria play in nature. This method endeavors to trace the past history of a water by means of a study of the bacteria it contains, in order to estimate the dangers of injurious contamination to which it has been exposed, and the extent to which natural processes of purification have been active in reducing those dangers.

In its application it involves the determination of the species of bacteria in the water, together with an, at least approximate, estimation of the number of individuals belonging to each one of those species present in a given bulk of the water.

Before proceeding to a more detailed consideration of this method, it appears desirable to give an outline of the technical steps taken in counting, isolating, and identifying the bacteria in water.

After the collection of the sample in sterile vessels, in such a way as to avoid its contamination with foreign bacteria, the first step in its examination is the preparation of "plate" or "roll-tube" cultures, which have for their object the separation, from each other, of the individual bacteria in the sample. This object is gained through the use of culture media which may, at will, be rendered either liquid or solid, without thereby endangering the vitality of bacteria scattered through them. The medium commonly used for this purpose is a jelly of considerable firmness, which has been rendered highly nutritious by the addition of meat extracts and peptone, and then rendered sterile by killing any contained germs with heat.

Definite quantities of the water are thoroughly mixed with several times their bulk of this jelly in a melted state, and the mixture then poured upon a cold, sterile, horizontal glass plate, where it quickly solidifies in a uniform layer, forming a "plate" culture; or the mixture is solidified in a thin, uniform layer upon the inner surface of a test-tube, by rotating the latter around its axis, held in a horizontal position, until the jelly has cooled. This, the "roll-tube," is a modification of, and serves the same purpose as, the "plate" culture.

By this mixing of the sample of water with jelly the

[1] Being the Address delivered before the New York State Medical Association, September 27, 1889.

bacteria contained in the former are separated and disseminated through the mixture, so that, when the latter becomes solid, each individual bacterium occupies a fixed, isolated position in the layer of solid jelly. If now these slates (or tubes) be set aside, under favorable conditions and protected from the intrusion of foreign bacteria, the bacteria contained in the jelly will multiply so rapidly that, in the course of a few hours, many thousand bacteria will have sprung from each bacterium originally imprisoned in the jelly.[1] But inasmuch as the descendants of each individual are confined, by the solid jelly, to the spot originally occupied by their progenitor,[2] it follows that in the course of time an accumulation of bacteria large enough to form a mass visible through the microscope, and later to the unaided eye, takes place at that spot. Such an accumulation is a "colony" of bacteria, and since it must necessarily be made up of individuals belonging to a single species,[3] it is a "pure culture," and serves as the starting-point of other pure cultures of the species in jelly or other media.

Fortunately, colonies of different species differ more or less in appearance, and in some cases species may be identified with considerable certainty by the gross or microscopic appearances of their colonies on the plate; but in most cases this is impossible, and the bacteria making up a colony must be submitted to further observation before it is possible to completely identify the species to which they belong.

After noting the facts which can be gleaned from an examination of the colony, small portions are removed by means of a sterile needle and planted in other culture media, where the growth of the species, as affected by differences in nourishment, temperature, and other conditions, may be observed. The colony on the plate also yields material for the preparation of stained or unstained specimens for the direct observation of the individual bacteria through the microscope, thus furnishing data as to their shape, size, mode of aggregation, and motility.

By procuring a sufficient variety of conditions under which the growth of a given species of bacterium is studied, it is possible to obtain enough data as to its characteristics to distinguish that species from all others. When this has been accomplished the given species has been identified.

The media in general use for these purposes are jelly, bouillon, agar-agar, a gelatinoid substance obtained from an oriental alga, potato, bread, and coagulated blood serum. All these media, except jelly, can be used for the cultivation of bacteria at the temperature of the body, without altering their physical condition, so that the modifications in the growth of the bacteria due to differences in temperature can be observed.

A question of a good deal of interest here confronts us: the question as to the proper conception of a species among the bacteria. Cultures of the same species may show considerable variations in their characters when subjected to different environments—variations so wide that they exceed what are in other cases regarded as specific differences. This question is too involved and technical for discussion on this occasion. For the purposes of the bacteriological test of water, the practical course is to regard any marked characteristic as specific. The object of the test being to enable us to judge of the past history of a water by means of the evidence furnished by the bacteria it contains, the particular conditions under which those bacteria have developed are a part of the knowledge we are seeking; and if variations in those conditions are recorded in corresponding modifications in the characters of the bacteria, those modifications may be as important to us as a real difference of species, and we may, therefore, provisionally, regard them as specific.

We have now rehearsed minutely enough, for our present purpose, the technical procedures involved in a bacteriological examination of water, and may now turn our attention to the nature and significance of the results obtained by their application.

If we trace the history of a given sample of water, we shall arrive at a point in that history when the water must have fallen as rain. Since water, when it evaporates, leaves behind it all suspended matter, it follows that any bacteria found in rain-water must have been washed from the air, or from the surfaces with which the rain came in contact. They were either in the atmospheric dust, made up of fine dry particles wafted into the air by currents, or they were upon the water-shed.

It so happens that bacteria are not all equally capable of preserving their vitality when subjected to the desiccation which must precede their presence in floating dust, and it follows therefrom that rain-water, except under extraordinary circumstances, will contain only species included in a group provisionally designated as "air bacteria," without implying that they are found only in the air. And, conversely, if all the bacteria in a sample of water are of species included in this group, the deduction that it has been exposed to none but aërial contamination appears reasonable, no matter how numerous the individual bacteria may be.

If we next imagine that the rain-water has fallen upon the ground and thence washed into streams, ponds, or open wells, it is evident that it will carry with it those bacteria which can be readily detached from the vegetation or the soil over which it has passed. In brook- or pond-water we may, therefore, look for not only air bacteria, but bacteria belonging to a second group of species representative of surface drainage.

While a portion of the rain-water runs from the surface, another portion sinks into the ground and eventually becomes blended with what is called the "ground-water." During its passage through the soil, most, and probably in many cases all, of the bacteria contained in it are caught in the interstices of the ground, or are subjected to unfavorable conditions and die. Observation has shown that ground-water is usually free from bacteria, or contains them in but small numbers; but when the soil is very pervious the ground-water may yield bacteriological results approximating those indicative of surface drainage.

The ground water underlies a layer of soil rich in bacteria, and is exposed to many chances of receiving them on its passage toward the surface, where alone it can be of domestic use. And it is during this passage to the surface that it is exposed to the greatest risks of contamination with sewage or excrementitious matter, which are especially liable to contain noxious bacteria.

In such a water the bacteriological test is capable of detecting the contamination and of determining its nature with considerable precision.

From a bacteriological point of view, admixture of sewage with a water can be injurious only when that sewage contains noxious bacteria. If, through any process, the sewage be freed from such bacteria, it will be deprived of all bacteric infectious qualities. The most common natural process by which sewage is freed of bacteria is filtration through the soil. If all the bacteria are removed the sewage can contain no pathogenetic species, but if they are not all removed and the sewage passes into a water-supply, the latter will be in danger of infectious contamination so soon as the sewage contains pathogenetic bacteria.

The detection of the contamination of a water-supply with sewage is of particular interest because of its relations to the possibility of infection with typhoid fever following the drinking of such a contaminated water.

We know of no general natural habitat of the typhoid bacillus. It may be that, in the future, some natural home or mode of development of that bacterium will be dis-

[1] There are species of bacteria incapable of growing in gelatine at ordinary temperatures. The presence of these species is ignored where gelatine plates are used for water analysis.

[2] There are exceptional species which swarm over the plate, so that distinctly isolated colonies are not formed.

[3] The certainty of this purity is proportional to the thoroughness with which the water was mixed with the melted jelly.

covered. When that knowledge has been acquired the bacteriological test of water can be applied so as to make practical use of it, but for the present we must consider the discharges from individuals suffering from typhoid fever as the source from which typhoid bacilli might gain access to drinking-water.

If the water were free from bacteria before the entrance of the typhoid bacilli, and the latter were not mixed with other species of bacteria, their detection would be simple and certain, and with the finding of them a bacteriological examination of the water would come to an immediate conclusion. But in actual cases the typhoid bacilli are associated with large numbers of fecal bacteria, and this mixture disseminated through a large bulk of sewage; the chances of identifying the typhoid bacillus are inestimably diminished by these circumstances, and we are, therefore, constrained to condemn water containing fecal bacteria, or those forms of putrefactive bacteria which are frequently found in sewage, even though they themselves may have no pathogenetic qualities, and even though the source of the water was apparently pure.

Simple and clear as are the principles underlying the bacteriological test of water, it does not seem superfluous to consider a few typical illustrations of their application to cases met with in actual practice.

I. A sample of water was found to contain an average of 496 bacteria in one cubic centimetre, a very large majority of which belonged to a single species—micrococcus caudicans—a very common air bacterium. There were but few other species present, most of which were recognized as common air species.[1]

The inference from such a result is direct: The water, a pure water, had been exposed to the air and then remained subject to conditions favorable for the development of the bacteria which had fallen into it until they had increased to the number found. This conclusion was confirmed by the fact that the sample, as was afterward learned, had come from a tank which was filled with water previously subjected to a very intelligent process of filtration. Some of this same water, after being bottled for a short time, contained 3,970 bacteria per cubic centimetre, among which five species were recognized, the majority of the individuals belonging to the single species caudicans.

No reasonable sanitary objection could be raised against this water, either before or after it had been bottled, although the number of bacteria found in both samples exceeded the usually accepted limit for good water.

Many of the air bacteria seem, after a time, to die out when introduced into water, as is exemplified by a sample of rain-water, which immediately after collection, during a gusty thunder-storm, contained 5,940 bacteria; while, after standing protected from dust for a few weeks, the number had fallen to two. On the first examination there was a large number of species present; on the second examination only a single species, common in both air and water.

II. Water from a sylvan brook, swollen after a heavy rainfall, contained over two thousand bacteria to the cubic centimetre, a large number of which proved to be bacillus subtilis, a species abundantly found on vegetation and in earth. There was also present a species frequently found in soil. No other species other than air species were found, and it was, therefore, concluded that the large number of bacteria was due to surface drainage innocent of injurious qualities.

III. A brook was examined at its source, where the water ran from a loosely covered cleft between two rocks; again about half a mile from its source, after it had wound through a grove and open fields; and again at a third point, about three-quarters of a mile beyond the second place of collection, and several hundred feet below a point where it received the drainage from some half-dozen dwellings.

[1] Bacillus luteus, yellow sarcina, micrococcus cereus flavus, and some not named.

At its source it contained 250 bacteria, among which there were several air species, a few of the more common water bacteria, also occasionally met with in air, and a few earth species.

Samples from the second point of collection contained 532 bacteria, similar in character to those at the source, but the water and soil species were relatively more abundant.

At the third point of collection the number of bacteria had risen to 4,773, and, besides the species found above, there were both fecal and putrefactive species present.

The correspondence between the results of the bacteriological examination of this brook and the history of the water is so close that, if we knew only those results and the order in which the samples came, we should be obliged to construct a history of the water essentially identical with that of this brook.

IV. The water-supply of a certain town is drawn from a series of driven wells, which are, with the single exception of one used for making observations on the level of the ground-water, connected in such a way that the water is pumped from them all collectively.

A sample of water taken from the main at the pumping-station contained two bacteria per cubic centimetre, while a sample taken from the observation-well contained five thousand. But the bacteria in the latter sample were all of one species—namely, the same species which has already been mentioned as persisting in a long-preserved sample of rain-water. According to our principles of interpretation, these samples must be regarded as equally free from suspicious contamination. The five thousand bacteria were due to an adventitious inoculation of the test-well with a harmless species capable of thriving under the conditions there prevailing. After stating that the bacteria present were of a single species, it is superfluous to add that the well was kept covered.

V. A deep artesian well, situated in the immediate neighborhood of a field irrigated with the sewage from a large public institution, was used as the water-supply for the inmates. The water had been repeatedly declared unsafe because of the high yield in total solids, chlorine, and ammonias obtained on chemical analysis. It was examined bacteriologically and found to contain very few bacteria, none of which represented species indicative of sewage contamination. There were no clinical indications that the water was unwholesome. In this case it appears that the natural filtration of the water through the soil sufficed to free it from bacteria.

VI. A stream which was drawn upon to furnish water to a town, was suspected of being contaminated with sewage because of an outbreak of typhoid fever in that town. Chemical analysis failed to furnish evidence of any such contamination, but the water was found to contain large numbers of bacteria belonging to a putrefactive species common in sewage. This result, while not demonstrating the presence of typhoid germs in the water, arouses a strong suspicion of a sewage contamination, which alone would be sufficient to declare the water untrustworthy.

In conclusion, it is evident that the bacteriological examination of a water cannot, save under exceptional circumstances, pronounce a direct verdict as to the sanitary value of that water. Its legitimate province is the discovery of the relations existing between the water and the natural or fortuitous distribution of the various species of bacteria. The significance of those relations must be determined by our knowledge of the causation of disease.

---

PROGRESS OF CREMATION.—There are now thirty-nine crematories in various parts of the world. Italy has twenty-three, America has ten, while England, Germany, France, Switzerland, Denmark, and Sweden have one apiece. In Italy there were two cremations in 1876; the number rose to fifteen in 1877, and in 1888 the number was 226. Since 1876, 1,177 cremations have taken place in Italy, while the combined numbers from all other countries bring the total only to 1,269.

## A FEW CLINICAL CASES SHOWING THE VALUE OF OXYGEN COMBINED WITH NITROGEN MONOXIDE IN THE TREATMENT OF PULMONARY AND OTHER TROUBLES.

By E. C. TITUS, M.D.,

NEW YORK.

In The Medical Record of July 6th there appeared a very able article by Professor W. Gilman Thompson, showing a series of experiments with oxygen upon animals, and the conclusions arrived at as a result of those experiments. The conclusions were in the main such as I have demonstrated repeatedly by clinical experience. In the treatment of pulmonary complaints the tendency at the present time is toward local medication. This arises principally from the general acceptation of the germ theory, which teaches in the main that diseases originate from micro-organisms, and the belief that from this it must follow, as a necessity, that these micro-organisms must be destroyed or rendered harmless to organized tissues, either as a means of cure, or as a prophylaxis to such a disease. For these reasons attention has been directed more particularly to the study of means whereby antiseptics or germicides may be made to reach disease-germs in the lungs more directly and safely than has hitherto been known.

If tuberculosis depend upon the presence of infectious organisms in the tissues, then certainly the most rational mode of treatment in phthisis must include the administration of antiseptic agents. The most powerful antiseptic known to science is oxygen, for in an atmosphere of oxygen it is impossible for disease-germs to exist.

It has been found by clinical experience that oxygen is less irritating and more readily absorbed when combined with a certain equivalent of nitrogen monoxide. The proportions that I have found most valuable are two parts pure oxygen and one part nitrogen. In order to obtain good results, it is of the utmost importance that these gases should be absolutely pure. Pure oxygen I believe to be too powerful an oxidizing agent when used alone; especially when there exists inflammation in the air-passages. In cases of poisoning from hydrogen gas, however, it is better to use it undiluted. Nitrogen monoxide is valuable as a modifier of pure oxygen, and has a soothing effect upon the nervous system. It renders the oxygen with which it mingles more assimilable, and hence more promptly available in the general system. The discussion at the New York Academy of Medicine, following the reading of Professor Thompson's paper, was interesting in showing how generally this agent is now being used by the most advanced men in the profession. Its usefulness as a therapeutical agent may be shown by quoting the remarks of those gentlemen who engaged in the discussion. Dr. J. West Roosevelt said that in the simple anæmia of girls he found patients do better under the use of oxygen in connection with administration of iron than under iron alone. That opinion was shared by Dr. Francis Delafield, expressed some months ago at the Academy. Like Dr. Thompson, he had seen marked beneficial results where the amount of breathing service was diminished. Dr. George L. Peabody was of the opinion that oxygen inhalations were most useful in certain maladies attended by extreme dyspnœa, such as catarrhal bronchitis, asthma, pleuritic effusions, etc. Dr. Beverley Robinson thought he had seen absolute proof of the direct, immediate therapeutic action of the inhalation of oxygen in anæmia, in conjunction with iron. In a very large number of cases digestion and assimilation were improved, and in so far as it did that, it seemed to have a wide field of utility. In phthisis he believed it had no direct curative effect, but he thought it proper to use it, because, first, it forced patients to expand their lungs; second, because there was reason to believe it might act in some degree as an antiseptic; third, that it was useful in improving the nutrition. In cases of phthisis with partial consolidation, with fever, night-sweats, and cough, the administration of oxygen will be followed by a decline of the daily temperature, subsidence of the night-sweats, improvement of appetite, and more perfect digestion and assimilation; patients are taught to breathe more perfectly, which is invariably followed by increased lung expansion. The method of administration is important. The patient should be instructed to expel as completely as possible the air from the lungs, and then inhale deeply, and after fully inflating the lungs it should be held as long as possible before being expired through the nose; there should be an interval of two minutes between each inhalation; this method is applicable to the treatment of phthisis and anæmia. In pneumonia it should be administered continuously from three to five minutes, and as frequently as the urgency of the case demands.

I quote a few cases taken at random from my note-book, which will suffice to show the general action of this agent.

Case I.—A gentleman, aged thirty, an actor by profession, slight in stature, family history negative, was obliged to remain most of the time in the Northwest, because of pulmonary trouble. Whenever he returned to his home in the East his trouble was invariably aggravated. A physical examination revealed the following condition: Consolidation of the left apex anteriorly as far down as the nipple line; also evidence of small cavity in the upper part, and moist râles throughout the lung; incessant cough, profuse expectoration of muco-purulent character, daily abnormal temperature, followed by profuse night-sweats, and rapid emaciation. Began inhalations of oxygen for from fifteen to twenty minutes twice daily. At the end of one week the night-sweats had materially diminished, cough less severe, and general condition much improved. At the end of six weeks' treatment he had improved considerably in general condition and weight. An examination of the lungs showed that the induration had very much decreased, no evidence of cavity, and almost an entire absence of râles. Physical examination at the end of ten weeks showed that the consolidation had entirely disappeared, no vestige of the former trouble remaining, and he was apparently a well man. No return of his former symptoms have developed up to date, which is now more than a year; the only treatment he received, other than the inhalations, was the iodide of iron.

Case II.—A gentleman, aged thirty-two, by occupation a civil engineer, of phthisical family; five years ago had an attack of pleurisy with effusion, which left a carnified condition of the upper part of the right lung. Three years later began to lose flesh; a cough from which he had never entirely recovered became worse, accompanied by profuse expectoration, rapid loss of flesh; daily temperature reaching as high in the afternoon as 103° F., followed at night by profuse sweating. Patient was advised to go to Colorado; after remaining there some months, without improving, he returned to New York thoroughly disheartened, having given up all hope of ever getting well. Placed him upon inhalations of oxygen and nitrogen monoxide, as in the former case. Its use was marked by an increase of the expectoration for the first week, after which time it gradually decreased; the appetite, which was entirely gone, improved rapidly; the afternoon fever and night-sweats disappeared at the end of the fifth week, with gradual improvement in the general health, and slight gain in weight. The breathing at the commencement of treatment, which under forced inspiration was very limited, painful, and accompanied by a disposition to cough, gave place to easier and painless respiration. Patient has been under constant treatment since November, 1888. The last two months he has been able to attend to his business daily, and has exposed himself repeatedly to inclement weather without any return of his former symptoms. A slight cough remains, which, I believe, is due to the presence of pleuritic adhesions. One thing further I would mention, the chest expansion under forced inspiration was increased from one and a half to three and a half inches.

Case III.—Young lady, aged twenty-three, suffering

from an extreme form of simple anæmia, which had resisted a thorough employment of the usual remedies, combined with good food and plenty of fresh air; was consulted because of amenorrhœa, loss of appetite, feeble digestion, and irregular action of the bowels; could not take proper exercise without marked dyspnœa. A thorough examination excluded all organic causes. Having tried iron, arsenic, and strychnine with but slight and only temporary improvement, I concluded to try inhalations of oxygen in conjunction with the above-mentioned remedies. To my satisfaction, and to the patient's great delight, improvement began almost immediately in the appetite, digestion, and assimilation; the pallor of the face gradually gave place to a healthful rosy complexion, with disappearance of the dyspnœa, and at the end of three months' treatment the menses were perfectly re-established.

In the treatment of pneumonia I have used the combination of oxygen and nitrogen monoxide with marked benefit. It quiets the action of the heart, greatly relieves the dyspnœa, enabling the patient to breathe more freely and deeply, and promotes free expectoration. The following case, taken from a number so treated, and cited because of its extreme form, will suffice to demonstrate the beneficial effects of this mode of treatment.

A gentleman aged sixty-three, of robust habit, was taken ill with double pneumonia. Recognizing the case to be of extreme gravity, because of the rapid respiration and the early development of delirium, with a rapid, feeble, and irregular pulse, I immediately began the use of oxygen and nitrous monoxide, with stimulants, and other remedies. At first the inhalations were given very frequently, as often as every fifteen or twenty minutes, and for a period of from three to five minutes at a time. After using a few times, the patient became more quiet, the breathing easier and less rapid, with clearing up of the cyanosis, and abatement of the delirium, and free expectoration. The remedies were continued through the night. The following forenoon patient expressed himself better, and very much relieved by the inhalations. The remedies were continued through the course of the disease, at either longer or shorter intervals, as the exigencies of the case demanded, and was always followed by an amelioration of the urgent symptoms. During the period of convalescence the patient seemed to gain strength more rapidly by a continuance of the inhalations, and made a perfect recovery. This case was seen with me in consultation by Drs. Thomas E. Satterthwaite and W. A. Shufelt, who heartily endorsed the line of treatment.

Sufficient has been said to show the efficacy of this agent in the class of cases above mentioned. Dr. Thompson cited in his paper the great benefit that was derived from the use of oxygen in the treatment of cholera, during the epidemic at Marseilles and Toulon in 1886. If such was the case, why should it not be a most excellent agent to be used in the treatment of cholera infantum, especially during the period of collapse? I am convinced that oxygen as a therapeutic agent has not received the attention that it merits, and I agree with Professor Thompson, that no consideration of expense should weigh against it.

153 West Tenth Street.

---

Massage in Rickets.—Dr. Silfverskiöld speaks very favorably of massage in the treatment of rachitis. He begins with the lower extremities, using considerable pressure in a direction from below upward, and making energetic passive movements of the ankle-, knee-, and hip-joints. He then passes to the abdomen, thorax, neck, and upper extremities, exciting increased respiratory movements by making pressure on the chest. Each séance lasts for from ten to fifteen minutes, and the treatment is continued through a period of from four to six weeks. At the beginning, the patient usually complains of pain during the manipulations, but this soon passes away. The author claims to have obtained excellent results in a number of cases.

## INTUSSUSCEPTION AND THE USE OF INJECTIONS.

By W. E. FOREST, M.D.,
NEW YORK.

In The Medical Record for August 3d is reported a case or intussusception in a child relieved by the use of sulphuretted hydrogen gas from a Bergeon apparatus. It is stated that this is the first case, as far as known, where the Bergeon apparatus has been used for this purpose in this State.

However admirable this method may be in the treatment of the condition in question, if another method can be shown to be as effective and more safe, more simple, and more scientific, the former should give way to the latter.

Without further introduction, I will suggest to Dr. Rodenhurst and the profession in general, a method that will meet the requirements mentioned.

In using injections of either gas or liquid to overcome intestinal obstruction, one ought, if possible, to know two things, namely: 1st. How much force (approximately) the intestine will stand without danger of rupture. 2d. How much force one is using at any moment in giving the injection.

As to the first point, a series of experiments made by me and detailed in a paper read before the New York Academy of Medicine, and published in the *Journal of Obstetrics* in 1886, would seem to show that it is not safe to use an injection with a pressure exceeding fifteen pounds to the square inch in a case of intussusception, and this only in adults. In infants the pressure should not exceed six or eight pounds to the square inch (see *Journal of Obstetrics*).

Now, with the Bergeon apparatus a greater pressure than the above might be used, I suppose. With the Davison syringe I have shown that a pressure of from thirty to seventy pounds to the square inch may be exerted on the intestine, and hence a very dangerous pressure.

The objection to the Bergeon apparatus, aside from the fact that one cannot measure and regulate the pressure accurately, is its cost and cumbersomeness as compared with the apparatus I have suggested in the article referred to.

In order to measure the pressure used in an injection, it is only necessary to remember that one atmosphere, or fifteen pounds to the square inch, supports a column of water thirty-three feet high; hence a column of water thirty-three feet high will make a pressure of fifteen pounds upon every square inch of surface at the base of the column.

Now, if this column of water be held in a rubber tube of ordinary size, after allowing for friction of the water in the tube, it will be accurate enough to say that every two feet of the column represents a pressure of one pound to the square inch; hence a rubber tube six feet long, filled with water and held vertical, will cause a pressure of three pounds to the square inch at its base; and a tube twelve feet long will exert a pressure of six pounds to the square inch at its base; and so on.

Now, apply this principle to a case of intussusception in a child, for instance. The surgeon, instead of sending to the nearest city for a consultant and a Bergeon apparatus, goes to the drug store or hardware store and gets a rubber tube twelve to twenty feet in length. Into one end is inserted a funnel; into the other a nozzle of a Davison syringe. In order that the injected fluid may be retained, a shoulder may be made on the nozzle about one inch from the end, by winding a roller-bandage around. This shoulder will retain every drop of the injection when pressed against the sphincter. Now a pitcher of warm salt-water completes the apparatus, and the father of the child is the assistant surgeon. The patient is taken into the hallway of the house, so that the requisite elevation may be gained, the child is etherized, the surgeon inserts the nozzle of the syringe and holds it in the rectum with

one hand, while with the other he manipulates the walls of the child's abdomen. The assistant pours the water into the funnel and slowly raises it, mounting the stairs at the time if necessary. When the funnel has been raised twelve feet above the level of the child's body, great care should be exercised, as the pressure is now about six pounds on every square inch of colon below the obstruction. It is seldom that a greater pressure than this will be needed to reduce a recent invagination. The pressure should be increased very slowly, as time is an important element in reducing an invagination.

If in any case the pressure mentioned above does not bring about the end aimed at, the pressure may be increased up to ten pounds to the square inch.

For further details as to the method and when to employ it, as well as for a simple and cheap method for generating gas and its use in reducing an intussusception, I must refer to the article in the *American Journal of Obstetrics* for 1886.

In that article are the histories of two cases of intussusception successfully reduced by gaseous and fluid enemata introduced from a syphon of Vichy water.

Since publishing the method for the use of a column of water, Dr. A. S. Hunter, of this city, has used the method successfully in a case of invagination in a child.

105 Waverley Place.

## Progress of Medical Science.

Parasites of the Blood.—A Russian scientific observer some years since discovered in the blood of birds animate bodies, of the nature of parasites, to which he has given the name of *Polimitus*, presenting a striking resemblance with the organisms described by M. Laveran as existing in the blood of persons attacked by malarial fever. Subsequent researches have shown that the presence of microbial parasites of animal origin in the blood is much more common than had been suspected, more especially in cold-blooded animals. Of warm-blooded animals, carnivora are more liable to be invaded by these intruders than others, but it is comforting to learn that, for the most part, their presence does not appear to entail any particular inconvenience. Only four or five out of three hundred birds examined, died in consequence of lesions caused by the parasites, and the pathological appearances were then identical with those observed in the subjects of malarial fever.—*The Medical Press.*

Thiol, a Rival of Ichthyol.—Ichthyol has found a rival in thiol, a new product of chemical synthesis, obtained by artificially sulphuretting unsaturated hydro-carbons, and charging these with ten per cent. of sulphur (*The Provincial Medical Journal*). Chemical and therapeutical researches prove its exact identity with ichthyol. Thiol consists of a brown fluid of the consistency of syrup; it is completely soluble in water, is totally inodorous, and has therefore a decided advantage over ichthyol. There exists also a dry thiol, which has two and a half times the strength of fluid thiol, otherwise having the same properties as the latter. Thiol is used like ichthyol in the following diseases: Acne, acute and chronic rheumatic arthritis, other rheumatic affections, contusions, decubitus, eczema, erysipelas, neuralgia, ischia, leprosy, frost-bites, prurigo, pruritus, ulcus, cruris, burns, and scalds. On the initiative of Schweninger, thiol was tried at the Charité Clinic of Berlin, and Dr. Reeps reports on these trials in a very favorable light, as does also Dr. Buzzi, whose opinion is based on an even more extended clinical experience. Dr. Reeps states that it may safely be concluded that thiol, externally applied in skin diseases, has positively the same effect as ichthyol. As their effect in these instances is identical, it may also be assumed that thiol will prove equally efficacious in other diseases where ichthyol has been employed. Reeps has taken internal doses up to two and a half grammes without discomfort or disturbance of the stomach; and he believes, therefore, that it is comparatively harmless. It has been asserted lately that this is not the case with ichthyol, but he ascribes the adverse physiological effects of ichthyol to its obnoxious taste and odor, and these are entirely eliminated in thiol. He does not consider there is any further doubt that thiol and ichthyol are two exactly identical substances, and that thiol will serve to replace ichthyol when the natural sources of the latter remedy become exhausted; even now the discovery may be recognized as a great boon, which makes us independent of nature's supply of this valuable remedy. The following are the usually prescribed formulæ:

℞. Thiol ..... 3j.
Vaselin ..... 3j.
Lanolin ..... 3j.
M. F. ungt. S.: For external use.

℞. Thiol sicc ..... gr. ij.
Pulv. glycyrrhizæ ..... gr. ij.
Glycerin. tragacanth ..... q. s.
F. pilula. S.: One pill to be taken three times a day.

℞. Thiol sicc ..... 3j.
Zinc oxid ..... 3ij.
Amylum ..... 3j.
Talc ..... 3ij.
F. pulv. S.: The affected parts to be dusted with this powder.

Male Fern and Calomel for Tape-worm.—In the treatment of tænia Dr. Duchesne strongly recommends male fern combined with calomel, according to the following formula:

Eth. extract male fern ..... 2 drachms.
Calomel ..... 12 grains.
M. Make 16 capsules, which are given two at a time, every ten minutes until all are taken.

The great advantage of this preparation is that the patient has nothing to drink, and that the purgative is taken along with the worm-medicine. For some people, especially women, capsules are difficult to take, in which case the medicine is perhaps best taken with molasses. Sometimes the capsules provoke colicky pains, but these can be avoided by taking twenty grains of antipyrin fifteen minutes before the capsules. With these capsules Duchesne has yet to experience his first failure, and he has already used them in hundreds of cases. Male fern is the only remedy that will successfully expel the bothriocephalus. The treatment of tænia in children is a difficult matter, but he has been regularly successful with the following plan: After fasting twelve hours, administer the following preparation to a child of five years:

Eth. extract of male fern ..... 1 drachm.
Calomel ..... 6 grains.
Sugar ..... 2 drachms.
Gelatin, q. s. to make a jelly of ordinary consistence.

The patient should be told to take an injection of salt water when the worm appears at the anus, and then sit over a vessel of warm water to float the worm and prevent it breaking from its own weight. The one point always to be remembered, on which success depends, whatever the vermifuge used, is the necessity of administering the purgative soon after the substance which stupefies the worm.—*The Weekly Medical Review.*

Menstrual Optic Neuritis.—Dr. E. Beck (*The Cincinnati Lancet Clinic*) has reported several cases in which optic neuritis has resulted from menstrual anomalies. He arranges them into several groups. 1. Cases which occur in young girls, when the menses fail to appear. 2. Cases which occur in young women, with tardy, scanty, and irregular menstruation. 3. Cases which occur in amenorrhœic women. 4. Cases which appear immediately after the sudden suppression of the menses from cold, fright, or any cause. 5. Cases caused by dysmenorrhœa. 6. Cases caused by metrorrhagia. There is finally a small group of cases in which chronic metritis has led to early atrophic changes in the uterus, scanty, irregular menstruation, and sterility.

ATHREPSIA: A WASTING DISEASE OF CHILDHOOD.—In the *Revue mensuelle des Maladies de l'Enfance* Dr. Legournet has published an article on athrepsia, a *résumé* of which appears in the *Archives of Pediatrics*. Athrepsia is a morbid condition of infants which is characterized by disorders of digestion and nutrition, and results in defective or improper alimentation. The most striking symptom in the physiognomy of an athrepsic patient is emaciation. The child loses weight rapidly, and may lose as much as twenty or thirty grammes daily. Parrot divided the disease into several periods and recognized several degrees in the gravity of the disease. It frequently begins at the end of the first week of life, the process of denutrition or innutrition being consecutive to that which existed at birth. If it is remembered that for the first few days after birth an infant normally loses thirty or forty grammes daily even with a good nurse, this loss being rapidly made up in the succeeding period, it is easy to understand how great the loss in vitality must be to infants who lose much more than that and then fail to gain correspondingly in the succeeding days. Such children may live from three to six weeks, being apparently at death's door all the time, and becoming more and more feeble and emaciated. In the grave form of athrepsia one may distinguish three periods—one which is marked by the phenomena of indigestion and by green diarrhœa; a second which is marked by vomiting, muguet, erythema of the scrotum, the thighs, and the anal region, emaciation, and chilliness. If suitable food be given it is possible to restore the child even from such unfavorable conditions. The third period is that of cachexia, and is followed by death from exhaustion or from complications which intervene. The rapid form of athrepsia is the most common one, the child succumbing in three to six weeks. In the slow form the child may even gain weight in spite of bad hygiene, and may reach the age of several months, dying without complications. The author distinguishes an acute athrepsia from the rapid variety by the fact that in the latter the infant has never been able to profit by the food which was given him, while the other made irregular progress, the regimen being tolerated for a while, and then giving rise to gastro-intestinal disorder. The latter will die unless suitable dietetic changes are made; the former may be able to exist without much change of diet if he survives the gastro-intestinal attack. But a child who survives this bad usage is very likely to show the effects of it in his physiognomy, his bearing, his functions, and his nutrition. Such children become rachitic, have pulmonary or other serious troubles, their teeth appear late and are badly developed, and the individuals themselves usually die young. The disease is easily diagnosticated. A child who does not digest at all, or digests badly, and instead of improving emaciates and loses weight, or gains very slowly, has athrepsia. Vomiting and diarrhœa are not the only symptoms, for such symptoms are present in simple enteritis or in gastro-intestinal disease, or in infantile cholera, for these are accidental conditions resulting from errors of diet, from heat, and indigestion. The digestive troubles in athrepsia are the expression of a morbid state which is brought about by a defective regimen. In order to thrive, an infant should gain twenty to thirty grammes in weight daily for the first four months of life. If he gains less than that, his condition may become a serious one at any time. The lesions in athrepsia are those of violent gastro-enteritis, ulcerations, ecchymoses, softening and granular infiltration of the mucous membrane of the digestive tract. Finally, there are thromboses, interstitial hemorrhages, and steatosis of the kidneys, lungs, liver, and brain, all of which indicate an acute or chronic inflammation of the digestive tube, and the trophic disorder which accompanies the final cachexia. The mortality from this disease is very great. In the author's district, which includes a population of four thousand, about one-third of the deaths under one year of age, and one-seventeenth of the total number of deaths, were from this cause during a given period. All the infants were bottle-fed. The statistics of the entire city of Paris were even more astonishing, for there nearly two-thirds of the infants are bottle-fed.

THE ELIMINATION OF MORPHIA BY THE STOMACH.—Dr. Alt, of Halle, gives his researches on the elimination by the stomach of morphia injected subcutaneously. Hitzig had noticed that a dog which had licked up the vomit of another which had been narcotized by morphia injection also vomited a short time thereafter. This led Hitzig to believe that, notwithstanding the very short time between the injection and the vomiting, a considerable portion of the injected morphia had been eliminated. Men do not all react in the same way to morphia—some vomit, others do not; and authors explain this by saying that a part of the morphia is converted, in the circulating blood, into apomorphia, or that the preparation used is impure. None of them seem to think that the vomiting may be a reflex act setting out from the gastric nerves. Dr. Alt made many experiments, and found that in dogs morphia injection caused, in a few minutes, vomiting, and that a considerable portion was eliminated as morphia by the stomach. Before the injection the stomach was carefully washed out, and at short periods after it samples were taken and tested. The conclusions at which he has arrived are the following: 1. After subcutaneous application of morphia, it is eliminated by the stomach. 2. This elimination begins in two and a half minutes, lasts for half an hour, and ceases in one hour. 3. The inclination to vomit begins when the morphia appears in the stomach, and may be prevented by washing it out. 4. The quantity thus eliminated amounts to about half what is injected. 5. Poisonous results are much lessened by washing out the stomach, and deadly doses were thus borne without harm. These propositions are true of dogs, and to a great degree also in man. The practical importance of these researches lies in the fact that washing the stomach will be found of the greatest use in opium-poisoning, and that the medical jurist should in future search for the poison in the stomach instead of the blood, even when it has been given subcutaneously.—*The Edinburgh Medical Journal*, August, 1889.

THE FOOD TREATMENT FOR INSOMNIA.—Dr. Eggleston says that most students and women who are troubled with insomnia are dyspeptic, and he has found it easy to successfully treat such cases without medicine. They are instructed to eat before going to bed, having put aside work entirely, at least an hour before. If they are not hungry, they should simply be instructed to eat; and if they are hungry, they should eat whatever they want. A glass of milk and a biscuit is sometimes all that can be taken at first, or a mashed potato buttered. In a short time the night appetite will grow, and the appetite will then need no particular directions. If possible, the night meal should be taken in another room than the sleeping apartment, and for men in the city it will be found advantageous to go out to a restaurant. The idea of going out for something to eat and having to wait a short time for it will excite the appetite. Before eating, however, a bath should be taken; I much prefer cold or cool baths, which should be given with a sponge or stiff brush, and the body thoroughly rubbed off with a coarse towel afterward. The bath need not be more than five minutes in duration. . . . After the bathing and rubbing, or after eating, a moderate amount of exercise should be taken. For this a few minutes with Indian clubs or dumb-bells is sufficient. Further than this, the patient should go to bed at the same hour every night, and arise at the same hour every morning. . . . There is a popular superstition that grown people should not eat immediately before going to sleep; that it will give them indigestion or nightmare, or both. Dr. Eggleston cannot see why adults should be so very different in this respect from babies. We know that young children awake at night, and must have something to eat before they will sleep quietly; and some children actually fall asleep with a nursing-bottle leaking into the

mouth. It may be true that digestion is carried on slowly during sleep, and that the digestive function is less active, but here one need not be in a hurry for the completion of the operation. The average person should be in bed seven or eight hours, which is time enough for the digestion of almost anything edible. In our American life, he thinks, the digestion carried on through sleep probably has the better chance for thoroughness.—*Journal of the American Medical Association.*

THE EFFECTS OF ACIDS ON THE FUNCTIONS OF THE STOMACH.—1. Acids throw down a considerable precipitate of mucus. 2. They increase the cellular elements of the gastric contents. 3. Their introduction is followed by butyric-acid reaction, most marked after hydrochloric acid. 4. Larger quantities of the acids result in a considerable effusion of bile into the stomach. 5. They stimulate the secretion of pepsin, but have no influence upon the secretion of hydrochloric acid. 6. Their long-continued administration is followed by marked diminution of the secretion of hydrochloric acid. 7. Even in large quantities hydrochloric acid produces no gastric disturbances. On the contrary, a continued administration of the acid is attended with a feeling of well-being. 8. The difference in the effect between acids and the alkaline salts on the gastric functions consists in the fact that the alkaline salts dissolve the mucus and decrease the secretion of pepsin, while the acids precipitate the mucus and increase the secretion of pepsin. The disappearance of the alkaline salts from the stomach is followed by a decided increase of the hydrochloric-acid secretion. This does not occur, or only to a slight degree, in the case of acids. Both the acids and salts, in large quantities in continued use, have the same effect in lowering the activity, and finally in destroying the function, of the glands secreting hydrochloric acid.—*Jaworski, in Centralblatt für Klinische Medicin.*

THE EXCRETION OF URIC ACID AND ITS RELATION TO MENTAL DEPRESSION.—In the London *Practitioner* Dr. Haig has published a paper on the relation between the excretion of uric acid and mental depression. The author has published his researches on the relation of certain forms of headache to the excretion of uric acid ("Medico-Chirurgical Transactions," vol. lxx.), and he now shows that the mental condition of many patients depends on the amount of uric acid in the blood. When the acid is in excess it produces marked depression or irritability of temper; when this excess passes off, there is a feeling of exaltation and sense of well-being. Many suffer from a certain amount of mental depression and heaviness at that time of the day at which the excretion of uric acid is normally at its greatest, that is, in the morning between breakfast and lunch, during the time the acidity of the urine is lowest. This corresponds in every way to the condition artificially produced by giving alkalies, which wash uric acid in excess into the blood, so inducing depression; by giving acids sufficient to counteract the alkalinity of the blood, the heaviness and depression will give place to feelings of well-being, mental clearness, and pleasure in living. When the blood is strongly alkaline, and in a condition to hold much uric acid in solution, all the symptoms of mental depression are present, and are more or less marked according to the amount of acid present, the excretion of uric acid in the urine being at the same time proportionally in excess of the average. When a dose of mineral acid has been taken the mental conditions clear up exactly in proportion as the uric acid is cleared out of the blood, and its excretion in the urine diminishes. When a dose of acid has been taken to cure a headache or a fit of mental depression, it is extremely common for some amount of shooting pain in the joints to be present while the acid is driving the uric acid out of the blood. By reducing suddenly the alkalinity of the blood in this manner, it is very common for the uric acid in the tissues of the joints to be deposited in the joints instead of passing off in the blood. In the treatment of cases of mental depression, where it is evident that the excretion of uric acid plays the chief part, it is not always certain that a dose of acid taken now and then will produce a cure; the prevention of the excessive formation must be aimed at by regulating the diet. A large amount of butcher's meat should not be allowed, but should be replaced by fish, fowl, and milk, and stimulants are to be avoided. In many severe cases the author has met with great success by insisting on a diet of bread, butter, milk, potatoes, and a large quantity of fruit, continued for weeks or months. At the beginning of this treatment the washing out of the uric-acid stores may be hastened by giving about fifteen grains of salicylate of sodium three or four times a day, or in some cases a dose of twenty grains every night is sufficient.

PUERPERAL ANÆMIA AND ITS TREATMENT WITH ARSENIC.—Dr. Osler (*Boston Medical and Surgical Journal* and *American Journal of the Medical Sciences*) says that of the twenty-one cases of pernicious anæmia of which he has notes, nine were in women, and in five of these the condition developed post partum. One of them he reports, by way of illustration. The patient began and continued to grow anæmic after confinement, could not sit up in bed without fainting, had constant vomiting and uncontrollable diarrhœa. Under the continued administration of Fowler's solution she steadily improved and became robust and of a good color, though iron had previously been given without any benefit whatever. The author then reviews the history of the employment of arsenic in pernicious anæmia, and calls attention to the fact that we do not fully understand the reason why the drug should be so useful in some cases and so useless in others. It certainly has often an effect in profound anæmia much resembling that of a specific; like that of quinine in ague, and iron in chlorosis. The initial dose should be five drops, increasing gradually to twenty or thirty drops three times a day. Puffiness of the eyelids, œdema above the eyebrows, vomiting or diarrhœa, indicate that the drug should be suspended for a time. Sometimes arsenious acid is well borne, when Fowler's solution disagrees with the stomach. The point of greatest importance is that the medicine must be given for long periods and in increasing doses. In post-partum cases recovery is always slow, and it is well to intermit arsenic for a few weeks; but it should be given at intervals for many months, even when the health is apparently re-established, as there is a well-recognized tendency to relapse in these cases.

FORMATION OF MELON-SEED BODIES IN JOINTS AND TENDON SHEATHS.—Considerable light has recently been thrown by Schuchardt on the mode of production of these bodies. After criticising the generally accepted views of their formation by fibrinous deposition, he gives at some length the results of his own microscopical examination of specimens that have come under his notice. His researches seem to show that the mode of their origin is essentially different from that which has been just alluded to. They either consist really of altered portions of the lining membrane of the walls of the cavity itself in which they are contained, or they are developed in connection with the tendon sheaths; while a careful examination of them shows that coagulated fibrin does not really enter into their composition. In more than one instance the lining membrane of the joint was found to be covered with a viscid substance more or less laminated in character, and here and there already causing adhesions to take place between the opposing surfaces of the joints. These glutinous masses appear to be composed of partially "necrosed" portions of the joint-wall, which, instead of passing away, remain connected with the wall and likewise become attached to one another. The movements of the surfaces of the joints upon each other then cause these bodies to drop into the joints, where they lie loose as melon-seed bodies, and if the joint is in a fairly healthy condition they may be evacuated, and leave behind a good and useful jolnt.—*The Practitioner*, June, 1889.

# THE MEDICAL RECORD:

## CONCERNING SUITS FOR MALPRACTICE.

JUDGING from what we hear from different parts of the country, suits for malpractice are becoming alarmingly frequent. There appears, in fact, to be an epidemic of them throughout the West.

The question, What is to be done under the circumstances? is one fraught with painful interest. To every thinking man one thing is always evident, that in order to protect the profession the persecuted members of it should not be allowed to suffer. The profession in any neighborhood cannot afford to allow a verdict to be taken against a defendant. We say this much with becoming earnestness and deliberation. The attorneys generally believe that the members of the medical profession always stand by each other in such trials. This is as it should be, because we can always give the benefit of the doubt to the right side.

It is a rule, to which there is scarcely an exception, that the surgeon (for it is he who is most frequently prosecuted) always does the best he can for the patient, be the latter rich or poor. No man would be foolhardy enough to do otherwise. Fortunately the court allows this in almost every suit that is brought, although alleged negligence on the part of the plaintiff is generally one of the important counts in the indictment. We are pleased to note that, in spite of the most strenuous efforts on the part of the prosecution, this charge is seldom substantiated. Most of the tenable charges are also based on unskilful treatment and gross ignorance of the requirements of the case. We say it for the comfort of those who may now be under the ban, that it is in the vast majority of instances exceedingly difficult to prove this. A distinguished author once truly said that the most directly opposite views upon any scientific question could be proven by competent authority. The lawyers know this, and the surgeon must profit by it. The burden of proof must always be upon the side of prosecution. The defence, being forced into the position of expecting no quarter in the fight, has a right to retaliate by giving none.

It is easy to see that, except for some outside help in the way of medical testimony, the prosecution will have no show. And here let us pause in commiseration of the man who can use his scientific knowledge and experience against his brother in time of trouble. To our mind there is never any exculpation for this, even if the persecuted man be a successful rival or the successful professor of another school. No motive, however personal or exasperating, can excuse such Judas business. The man who is persecuted always has our pity, but the wretch who lends his ammunition to the enemy richly deserves the contempt of every fair-minded medical man. By his attitude in fouling the nest in which he is hatched, he may so load his own wings as to cripple his flying forever—and he generally does. If this Judas element could be eliminated, very few, if any, indictments would be possible.

In some charity for such personages, we are willing to admit that they are sometimes compelled to take opposite sides by their open criticism of another's work. Nothing is easier for an envious brother, afflicted with *caput tumefactum*, to magnify his office at the expense of the misfortune of a rival. Of course, when caught up by the shystering lawyer, it is too late to escape from wrongdoing, and he is expected to swear to the point with directness and force. It is then the last and only resource of the traitor and sneak. There is one such in almost every malpractice suit. So much, then, for the so-called professional expert on the other side.

It is a comfort, however, to the defendants to know that very few verdicts are rendered against them. We are speaking now of properly qualified men, who should not be blamed for bad results. The law expects of no qualified man more than he can do, with the use of his best judgment and skill, in the treatment of any case. If the case goes wrong he has the opportunity of explaining the fact by contributory negligence on the part of the patient, bad constitution, unfavorable surroundings, forced operation, and many other qualifying circumstances which might tend to a bad result despite the most scientific treatment. Indeed, if the practitioner even uses ordinary intelligence in the management of his case, he is entitled to the benefit of a doubt, especially if he wisely refrained from guaranteeing good results.

There are no cases more fraught with trouble for the practitioner in regard to suits than those of fractures and dislocations, particularly in the neighborhood of joints. Nine-tenths of all the malpractice cases would come under one or other or both of these heads. Generally speaking, the severe and complicated cases are very difficult of diagnosis and very hard to treat, and although the result may be, on the whole, satisfactory to the surgeon, it is far from being so with the patient's friends and with professional rivals. How easy it is for the man who was not there to say what the man who was there should have done. And yet, when the cases are examined from all points of view, and all the mitigating circumstances taken into account, it is found in ninety-nine cases out of a hundred that the results are exceedingly good if not brilliant. Most of the mistakes, when they are made, are in the direction of diagnosticating fracture for dislocation and treating the case accordingly, or at least of ignoring the possibility of a dislocation combined with fracture. This is, of course, very bad, but even in the worst cases such errors, in view of the great difficulties in diagnosis, are scarcely to be avoided. All these are considerations which naturally come up in the general discussion of such a subject, and may the better help us to appreciate the true force and inwardness of the following suggestions:

Always be certain of the diagnosis, and share the responsibility with counsel, if possible. Never guarantee good results, but always give a guarded prognosis. It is

always safer, in view of possible results, to treat the case as a serious and important one rather than otherwise. Never appear to be lacking in prompt attention to every possible requirement of treatment, and always be ready to warn the patient of the ordinary mishaps, shortening and deformity in fractures, the dangers attending operations, and the like, that there may be a proper division of risks and responsibilities. Be always on your guard against contributory negligence on the part of the patient. Promise him but little, and he will not be led to expect miracles. And, lastly, remembering that you, too, are mortal and liable at any time to err yourself, never criticise the work of your brother practitioner, and never under any circumstances consent to appear in court against him. This latter is a rule to which there can scarcely be any exception.

## THE NEW BUILDING FOR THE ACADEMY OF MEDICINE.

THE laying of the corner-stone for the new building of the Academy of Medicine during the present week will mark an era in the medical history of New York. It must be considered a starting-point in a direction for lasting good to the medical fraternity of this metropolis. The profession will now have a home worthy of itself, and can command that respect and influence which will necessarily grow out of a unity of purpose and dignity of work—eminently fitting to its high calling and noble aims. From a few good men and true, who first joined interests in 1847, and who met until lately in hired halls, it has increased its membership to that of a large and influential body, and will soon own an edifice which, in appointments and fitness for scientific work, will have no equal of its kind in this or any other country.

The Academy has earned its own right to its present position. Since its organization it has done an amount of faithful scientific work of which any similar society should be justly proud. Its proceedings have been marked with dignity, learning, and interest, and the papers and discussions before it have gained a reputation for American medicine throughout the world. It has been, in essence and in fact, a scientific society, which has not cared to meddle with medical politics, or in quarrels based on real or fancied ethical rights. Pursuing the even tenor of its way, it has sought with an effectual and honest purpose to gather under its influences the best elements for good which dignified science can bring to bear on good fellowship, and friendly emulation can suggest. Ever since its beginning it has maintained this course. Its past experience cannot fail to foreshadow its future.

There is great reason for congratulation in all this. But, at best, the profession of this city must not allow itself to say more than that it has made a good beginning. A great deal of work lies before it to keep up the reputation of the Academy for good work and good deeds. It must be admitted that the profession is willing to do its part. But there is still something more to be done by the laity. Liberal donations have already been made by lay friends of the Academy, but the funds are not yet all subscribed for. We only wish, in this connection, to state the fact that fifty thousand dollars is yet required to enable the medical profession to feel really at home in their prospective building. There is no argument needed for a full realization of the beauty of charity on the part of the friends of the Academy. The Academy has shown itself in earnest as to its desire for a suitable home, and the time has come for the rich men in and out of the profession to prove their substantial sympathy in the laudable and necessary movement. Who will be the benefactors? Science and humanity stand ready with their benediction.

## OUR ILLUSTRATION OF GERMAN MEASLES.

WE present in this issue another of the fine plates from Morrow's "Atlas" illustrating one of the common eruptions met with in general practice. It is only within later years that Rötheln was considered a distinct form of measles, and the interest in its study has developed accordingly. The prominent feature of the disease being the eruption, occasion is taken for the delineation of the latter in the admirable coloring as shown in the plate. The pale rose hue is well portrayed, as are also the size, shape, and general arrangement of the papules. On the whole, it is an instructive object-lesson of a lesion the associated symptoms of which are worthy of study. As a work of art, it ranks with the beautiful and life-like representations of scarlet fever and measles previously published in THE MEDICAL RECORD, and likewise taken from Morrow's admirable "Atlas."

## THE LATE SESSION OF THE NEW YORK STATE MEDICAL ASSOCIATION.

THE recent session of this Association was characterized by an exceptionally large attendance, and much manifest interest in the proceedings. The topics discussed made a home-like appeal to the general practitioner, whose zeal is in the direction of "the first care;" they were practical, well-selected, exhaustive, and scholarly. Many new men, destined to make their mark, surprised both themselves and others with the applause gained by their ambitious endeavors and the results of their work. There were some disappointments, owing to the failure of a rather crowded programme and the absence of certain advertised participants, but, on the whole, these drawbacks were more than compensated for by the eagerness of volunteers to fill the gaps, so that there was no real dearth of substantial material.

The set discussions on the collective-investigation plan, which seem to have come to grief across the ocean, were both satisfactory and successful. The themes selected, such as "Tubal Pregnancy," the "Treatment of Hernia," and the "New Hypnotics," were timely and well treated. We may say, in fact, that they were exceedingly well handled, and, so far as the detailed questions were concerned, assigned to those who were able to speak by authority. There were very little crudities of thought or looseness of statement, but, on the contrary, much honesty of investigation, some sceptical interrogation, and a deal of logical candor.

Much as we have deplored the Code schism, we are fain to acknowledge that, when families become too large, the component individuals may gain in energy and benefaction by separating for the purpose of house-keeping on their own account; at all events, in the present instance, sympathy appears to drift somewhat toward the young couple, especially when zeal and honest endeavor go hand-in-hand. Certainly, if the Association aim for influence and additions to our stock of knowledge, not only

the profession but the public at large cannot fail to be benefited—the field is large, the harvest ripe, and the laborers none too many.

### SUGAR OF MILK AS A DIURETIC.

At a recent meeting of the Academy of Medicine of Paris, Dr. Germain Sée referred to the diuretic action of milk, and proposed to study this property more closely, in order to see upon what constituents of this substance the action in question depended. That the increased diuresis was not the result simply of the ingestion of a larger amount of fluid, was shown by the fact that the excretion was much in excess of the quantity of milk taken.

Arguing by exclusion, M. Sée came to the conclusion that it was to the sugar which it contained that the milk owed its diuretic properties, and he then put his theory to the test by giving sugar of milk to a number of patients suffering from dropsy. In some cases the diuresis was prompt and very pronounced, in other cases the amount of urine was very slightly, if at all, in excess of what it had been before the beginning of the experiment. This discrepancy in the results was found to be due to different causation of the dropsy. When the trouble was purely cardiac, with but little, if any, disease of the kidneys, the remedy was certain in its effects; but when there was extensive renal disease, but little diuretic action was noted. In cardiac dropsy, the author believed sugar of milk was the best and most certain diuretic that we possessed, the excretion of urine caused by it being greater than that due to any other drug. He found that it acted similarly to, though more powerfully than, caffeine, while possessing none of the disadvantages of the latter remedy.

Lactose acts, however, solely upon the kidneys, and is only of service in relieving the dropsy of heart disease, being without effect upon the dyspnœa. For the latter, M. Sée resorts to iodide of potassium, which may be given at the same time with the sugar of milk. The ordinary dose of lactose, in order to obtain the most certain diuretic action, is about three ounces in the twenty-four hours.

### UNIFORMITY IN REPRINTS.

Dr. Charles Everett Warren has been writing, in the *Boston Medical and Surgical Journal*, regarding the inconveniences that accrue to those who write in medical journals, and to the collectors of pamphlets, from their very varying size. The *Pittsburg Medical Review* has taken the matter up and attempted a solution of the trouble. It finds that the columns of forty American medical journals measure from 2⅜ by 7⅞ inches to 4⅞ by 7⅝ inches. It is suggested that by the adoption of two regular sizes an absolute uniformity of publication can be secured. A page 5½ by 8¼, which may be called size No. 1, would sufficiently serve all journals whose column width is from 2⅜ to 3⅜ inches, inclusive. This would leave a margin of 1⅜ inch for the smallest column and ⅜ of an inch for the largest, ample space for binding and for the good appearance of the page. Of the forty journals noted, sixteen would come within this form. For the remainder, a page 7¼ by 10 inches would prove satisfactory. This size, which may be called No. 2, would allow of a double column in all journals whose column width is 2¾ inches or less, and a single column for all of those 4 inches or more in width.

We would say that contributors to The Medical Record would have to order a size slightly larger than No. 2, since its page measures 3⅜ by 10½ inches. Reprints can, however, always be made of such style as the author of the article desires.

## News of the Week.

Dr. Beard's Work on Neurasthenia, which was translated into German by Dr. Neissier, has just reached a third editon.

The Next Congress of American Physicians and Surgeons.—At a meeting of the Executive Committee of the Congress of American Physicians and Surgeons, held in Philadelphia, September 21st, Dr. S. Weir Mitchell was elected president of the next Congress, which will be held in Washington in September, 1891, Dr. W. H. Carmalt, of New Haven, Secretary; Dr. J. S. Billings, of Washington, Treasurer; Dr. William Pepper, of Philadelphia, Chairman of the Executive Committee; and Dr. S. C. Busey, of Washington, Chairman of the Local Committee of Arrangements.

Dr. I. Minis Hays has retired from the editorship of the *Medical News*, and Dr. Hobart A. Hare succeeds him. Dr. Hays, we are glad to learn, will continue to edit the *American Journal of the Medical Sciences*.

Execution by Electricity.—At a recent meeting of the Paris Academy of Sciences a communication from Mr. Edison was read respecting the use of electricity as a means of inflicting capital punishment. He is of opinion that an alternative current will cause death without pain, but he adduces no experimental evidence in support of that contention. The matter was referred to the Medical Section of the Academy, which is to have the assistance of M. Marcel Desprez, the electrician, in drawing up a report on the subject.—*British Medical Journal*.

The Celebrated Painting of Rembrandt, called the "Anatomical Lesson," has been bought, it is said, by Mr. Ellesworth for the Institute of Art, of Chicago. It formerly belonged to the Princess de Sagan.

Transplanting a Chicken's Cornea.—The *Progrès Médical*, July 13, 1889, announces that Dr. Gravenigo, of the University of Padua, has been successful in an operation which has been tried hitherto in vain in France and elsewhere. This operation consists in grafting the cornea of a chicken upon a human eye. The graft was made recently, and the cornea is said to be very transparent, shining, and convex.

Medical Examiners for Tennessee.—The Governor of Tennessee has appointed the six members of the State Board of Medical Examiners, and they have organized with Dr. James B. Murfree, of Murfreesborough, as president, and Dr. T. J. Happel as secretary. According to the law not more than four members may be appointed from the same school of practice. In addition to the above there have been appointed Dr. E. E. Hunter, of Elizabethtown, and Dr. Heber Jones, of Memphis; with Dr. W. B. Halbert (eclectic) and Dr. T. H. Hicks (homœopath).

THE STATE EXAMINATION OF MEDICAL STUDENTS.—The law, passed last winter, requiring students having no baccalaureate degree to be examined before entering upon medical study, says the New York *Medical Journal*, is being put in train for enforcement by the Regents of the University. A circular, dated August 20th, has been sent to the colleges and to individuals giving information respecting the methods of these examinations. The secretary, Professor Melvil Dewey, may be addressed at Albany for copies of the circular. Students who had entered upon a three-years' course prior to June 13, 1889, are not affected by the new law. The earliest date for which an examination has been set down is September 30th, at Buffalo. Hence, we judge, a certain proportion of this year's entries at the colleges will be in the plight of a legal oversight, unless there happens to be some provision that is not explicitly stated in the circular of the Regents. However, as it is not the object of the act to lay a hardship upon the students of the current term, there will probably be no difficulty in obtaining an amendment from the next Legislature by which their cases may be passed upon equitably. It is not generally known that the Regents' certificate is required to be filed with the dean or secretary of the medical school "prior to entering upon the prescribed three-years' course of study of medicine," and without this preliminary filing it is forbidden to the schools to grant the degree of doctor of medicine. The act does not apply to persons who "have already entered upon" the said course of study. The word "already" must be construed to refer to the date of the approval of the act by the Governor, on June 13, 1889.

PROFESSOR BRIEGER has received the sum of fifteen hundred marks to enable him to prosecute his studies of the ptomaïnes.

A VERY BOLD EXPERIMENTAL OPERATION for the relief of the myxœdema which has followed complete removal of the gland is now under trial. It consists in inserting a fresh, healthy piece of the gland in the abdominal cavity, with the hope that it may form attachments and perform its mysterious function. In one case, probably by pressure upon the large intestines, the inserted mass, after the complete healing of the wound, caused such violent colicky attacks that it had to be removed, but in most instances no evil effects have followed the insertion. What becomes of the transplanted gland is not yet known. A case was recently shown that had been operated upon about three months previously, in which the presence of the gland in the abdomen could apparently be still demonstrated by palpation, etc., and in which, the patient asserted, his general condition was much better than before the abdominal section.—*Therapeutic Gazette.*

FIGHTING A SUPPOSED "MEDICAL TRUST."—The following item is copied from the *Evansville* (Ind.) *Courier* as an example at once of clear English expression and intelligent economical science. "It has become customary with all corporations, societies, companies, and many private individuals, when they have a job of building, repairing, painting, glazing, papering, printing, or any work to do, to ask for bids for the same. This has become so common that a large number of citizens have lately joined together for what they claim is self-protection, and will soon hold a mass meeting to act upon measures already proposed for mutual protection. Among these the one most necessary is some means to protect themselves against what they claim to be the exorbitant charges of the medical trust. To do this blanks will be given to the heads of families for the purpose of getting bids for attending their families by the year or by the job, as they may deem best. This seems to be a good move, if carried out properly, and should include, besides the physicians, preachers, lawyers, and all other professions and artisans that have formed trusts, and thus a revolution will occur that all would gladly see succeed."—*Boston Medical and Surgical Journal.*

DEPOPULATION OF FRANCE.—The movement of population in France indicated by the summaries published for 1888 in the *Journal Officiel* cannot be read without regret. They are summed up pithily by M. Georges Michet in a few words: Diminution of marriages, augmentation of divorces, decrease of legitimate births, increase of illegitimate births, excess of deaths over births in forty-four departments. But for illegitimate births, the population of France would decrease.

DR. DUTZE, formerly assistant in Dr. Unna's clinic at Hamburg, has been invited to proceed to Honolulu by the Hawaiian Government, and to remain there some time to study leprosy and to investigate the effect of new methods of treatment.

SEVERAL OF THE MEDICAL JOURNALS OF PARIS have united to form a protective association. Over thirty journals have already become members, many of which are well known on this side of the Atlantic.

A MISTAKE THAT PREVAILS IN BOSTON.—The *Boston Medical and Surgical Journal* says, aphoristically but heterodoxically: "Woman has some organs outside the pelvis."

TRIED THE ELIXIR WITH STARTLING RESULTS.—Dr. Slominski experimented with the famous Brown-Séquard elixir of life in his rooms, 507 South Thirteenth Street. Both subjects were middle-aged men who had suffered strokes of paralysis. The first man was J. E. Bruner, and the second was Tim Kelley. The *modus operandi* consists of piercing a hole in the arm and then expelling the air, after which the elixir is injected. Mr. Bruner stood the operations wonderfully well, but Mr. Kelley did not. Kelley turned almost deadly sick, and gonorrhœa immediately set in, but was checked by the physician.—*Omaha Dispatch.*

A RARE ANOMALY: ABSENCE OF PECTORALS.—As is known, there exists a curious "law" according to which very rare or exceptional cases of biological anomalies (diseases or anatomical defects) tend to occur in groups. The "law" is once more well illustrated by the congenital absence of the pectoral muscles. As your correspondent stated in his preceding letter (*vide* the *Reporter*, July 13, 1889, p. 44), the literature of that extremely rare anomaly had been recently supplemented by Drs. Schulthess, of Zurich, Kobler, of Vienna, and Bradel, of Sophia (Bulgaria), who had published each a case almost simultaneously and quite independently of each other. A few days after my letter had been mailed to Philadelphia I received a current number of the "Proceedings of the Omsk (Siberian) Medical Society," No. 3, 1889, which contained

LINDNER, EDDY & CLAUSS, LITH. N. Y.

another instance of the defect, described by Dr. Nikolai A. Tüberovsky, house-surgeon to the Küldjinsky Lazaretto. The case is that of a young, strong, healthy, and otherwise perfectly well-developed Siberian Cossack, twenty years of age, in whom an accidental examination revealed a congenital absence of the sterno-costal portion of the right major pectoral muscle, as well as of the whole pectoralis minor, accompanied by an anomalous inability of the corresponding acromio-clavicular joint, the right clavicle and acromion being longer and thicker than the left ones. No functional disturbances were detected. Dr. Tüberovsky adds that Professor W. A. Gruber, the illustrious Russian anatomist, had seen only one similar case (absence of the clavicular portion of the major pectoral) during his forty years' practice, and Professor Lesshaff, of St. Petersburg, only two (absence of the sterno-costal portion).—Berne Correspondence of *The Medical and Surgical Reporter.*

## LAYING OF THE CORNER-STONE OF THE NEW BUILDING FOR THE NEW YORK ACADEMY OF MEDICINE.

THE New York Academy of Medicine laid the corner-stone of its new building at 17, 19, and 21 West Forty-third Street, on Wednesday afternoon, October 2d, with the assistance of Bishop Potter, the Rev. John Hall, Grover Cleveland, Drs. A. Jacobi and A. L. Loomis, and an audience of several hundred persons. The medical profession turned out in force and filled every space within hearing distance of the speakers. The platform was occupied by officers and ex-officers of the Academy, with the distinguished laymen who were invited to participate in the ceremonies. Among the medical gentlemen on the platform were Drs. Fordyce Barker and S. S. Purple, ex-Presidents of the Academy, Gouverneur M. Smith, George A. Peters, S. D. Hubbard, W. H. Draper, F. N. Otis, A. M. Jacobus, F. A. Castle, Alexander T. Hunter, C. A. Leale, and George F. Shrady.

Bishop Potter opened the exercises with a prayer, and the address was delivered by Dr. A. Jacobi, an ex-President of the Academy and the Chairman of the Committee on Funds for the new building (see page 365).

### ADDRESS OF EX-PRESIDENT GROVER CLEVELAND.

Mr. Cleveland's remarks followed Dr. Jacobi's address. He congratulated the members of the Academy upon the occasion that brought them together, and declared that it signalized an important step in advance for medical science, wrought by their activity and enterprise. He referred to the fact that he had lately seen a statement printed by the Academy only three years ago, in which it was set out that the aim of the organization since its formation had been the acquisition of a building for its use and the accommodation of its library, and that a commodious building had at last been obtained, and afforded all the room the organization was likely to need for some time. It was a remarkable evidence, he thought, of the success of the Academy that that building, so commodious only three years ago, had now been outgrown, and one three or four times as large was about to be substituted for it.

"The nobility and sacred character of this mission have been often dwelt upon," he said. "It is an old story, but it will never lose its interest while humanity is touched with human woe, while self-sacrifice receives the homage of Christian hearts, while the sufferings and sorrows of our fellow-men start the tear of pity, nor while their alleviation brings comfort and satisfaction to the soul of sympathy. All your fellow-citizens may well claim a share, not only because they are interested in the promotion of the science and art of medicine, by reason of their liability to accident and disease, but because such advance in any profession as is here demonstrated adds to the glory and renown of our common country. I am here to claim for the laymen among your fellow-citizens a part of the pride which grows out of the progress and achievement of our medical profession. I base this claim upon the fact that in this favored land of ours all interests are so interwoven and all activities lead, or should lead, so directly to the accomplishment of our common national destiny, that none of us can be indifferent to an important advance among us in any science or industry.

"I am sure that you are not inclined to ignore the aid you have received in the project you have undertaken from the laymen among your fellows. Nor can you forget that, underlying all that you have done and all that you have received, are our free American institutions which encourage and give scope to every worthy effort, and which offer fitting rewards for intelligent and well-directed labor in every condition of life.

"You will not, therefore, I trust, deem it impertinent if I remind you that none of us are absolved from the duty of aiding in the maintenance in complete integrity of these free institutions, and that this requires the thoughtful care and attention of every citizen. You do much for your country when you raise the standard and enlarge the usefulness of your profession, but you do not accomplish all you can, nor do you discharge your full duty of citizenship, unless you also attempt to better the condition of public affairs, and give to political topics and movements the benefit of your trained thought and well-informed judgment. In this way you assist in making safe and sure the foundations upon which must rest the success and value of all your professional efforts and accomplishments.

"I hope, when we shall celebrate here the discovery of our country [applause], that we may point out on this spot, in your completed building, a splendid monument of the progress of our medical education; a monument which shall not only prove to the stranger that our physicians are proud of their profession, but one which shall also be a reminder that those who govern within its walls do not forget, in their devotion to the science and art of medicine, their other duties of citizenship."

The President, Alfred L. Loomis, then conducted the imposing ceremony of laying the corner-stone, expressing the hope shared by the multitude present that the act was the harbinger of a brilliant future for the Academy and for the science to which it was devoted. Dr. John Hall pronounced the benediction.

### THE NEW BUILDING OF THE ACADEMY.

The New York Academy of Medicine long since outgrew its house at No. 12 West Thirty-first Street, and the need for a larger building has been frequently talked of. The money with which its present house was bought was almost wholly derived from members of the medical profession, and it was only by the exercise of a scrupulous economy that the society was able to pay off the mortgage three years ago, and maintain its free library and reading-rooms. With the recollection of forty years of effort to acquire a suitable meeting-place for the profession, it was not a matter of slight importance when Mrs. Charles Woerishhofer gave to the Academy, through Dr. Jacobi (then the President), $25,000 as a memorial of her husband, to be applied to the procuring of a larger and better building. From this moment the agitation of the project, which will result in the new building here described, became active, and it was not long before information was received that Mrs. Celine B. Hosack had bequeathed to the Academy $70,000, also to be applied to the erection or purchase of a new building, with the sole condition that a certain part of the building so acquired should be distinctively recognizable as a memorial of her late husband, Dr. Alexander Hosack.

With these two handsome gifts, and the value of its present building, there seemed no reason why the Academy should delay action, and a large subscription committee

was appointed, embracing several well-known citizens of other professions, and more money was asked for.

A smaller committee was appointed to look for a site, and for more than a year efforts were made to obtain a location which would be acceptable. Owing to differences of opinion, and the scarcity of eligible sites, and, perhaps, quite as much to the want of assured means, there was some delay in arriving at a choice; but finally the one selected seemed to all immediately interested to be the most desirable. A purchasing committee was appointed, consisting of the President, Dr. Loomis, and Drs. Herrick, G. A. Peters, and Castle, which committee was subsequently made a building committee, Dr. Jacobi being added.

Several eminent architects were at once asked to submit preliminary plans; and the excellence of all of them necessitated several meetings of the committee for a choice. Finally the plans of Mr. R. H. Robertson were accepted, and, with slight modifications, are the ones now being followed.

It had been proposed to use fire-proof construction for the library and assembly-hall only, but it was ultimately decided to make the entire structure fire-proof, notwithstanding the increase in cost.

The new building here represented is on the northern side of Forty-third Street, about two hundred and forty-five feet west of Fifth Avenue. Between it and the Avenue the Century Club is now erecting a house covering a plot one hundred feet square, and between the two buildings is that of the St. Louis College. To the westward of the Academy site the adjoining lot has since been bought by a gentleman with a contract to erect a first-class private residence, and the next fifty feet, running through two hundred feet to the southern side of Forty-fourth Street, is being negotiated for by a syndicate of art societies, with the intention of erecting a building which will accommodate them with rooms and furnish extensive galleries for exhibitions.

The proximity of the railroad depot; the stations of the Elevated Railroad; the horse-cars on Forty-second Street, Madison and Sixth Avenues; and the stages on Fifth Avenue, make the site as nearly central as it is possible to obtain, and there is little doubt that it will remain so for many years to come.

The new building covers a plot 75 x 100 feet, and has a basement, four full stories, and two half-stories. Its front is entirely of red sandstone, of fine texture, up to the spring of the arches of the second story windows. From thence brick-work will be introduced in increasing proportion until the apex of the gable is reached, where the finale is of carved stone-work.

There will be an assembly-hall 42 x 57 feet; a conversation- and smoking-room 26 x 36; five rooms for meetings of sections of the Academy and medical societies, besides the large hall; four toilet-rooms, a reception-room, coat-room, eight committee-rooms, ante-rooms, apparatus- or specimen-rooms, and private study-rooms; a reference library 37 x 43; a stock-room with a floor area of 1,882 square feet, two small rooms for the use of the librarian, a strong room for the storage of valuable books and papers; three reading-rooms 25 x 28; a laboratory or microscope-room 28 x 28; a dining-room or banqueting-hall 28 x 31; and a kitchen beneath it of about the same size, with serving-rooms attached; making altogether thirty-three rooms exclusive of halls and passageways, and the rooms in the basement used for air-chamber, coal, boilers, engines, unpacking books, etc., as well as the apartments for the resident librarian in the upper part of the building.

The entrance, on the side toward Fifth Avenue, is but a step or two above the sidewalk. A central stone column supports a flat arch which admits to an outer vestibule about 8 x 20 feet. An inner vestibule, about 6 x 10 feet, leads to a staircase-hall 15 x 33 feet, having on the eastward a reception-room 11 x 13 feet, and in its rear a coat-room 8 x 13 feet. A well for the rear staircase and elevator 14 x 20 feet brings us to the rear end of the hall. To the westward, on entering, opens a doorway to a committee- or reading-room (which can be used as an extra coat-room) 15 x 27 feet; beyond that is a passage to the smoking- and conversation-room of 26 x 36 feet, intended for the use of fellows who do not desire to enter the assembly hall or library. The next opening to the westward is that to the assembly-hall, and adjoining it, at the northern end of the staircase-hall, is the door to the banqueting-hall. The assembly-hall and banqueting-room adjoining, and the wainscoted partition of the latter on the side toward the assembly-hall, is made to be raised into the wall above so as to throw the two halls into one. So, too, the 14 feet doorway between the assembly-hall and the smoking-room can be opened on the occasion of an audience of unusual size, and about a hundred additional sittings within view of the speaker be secured. The ingenious manner by which a large space can be seated on occasions, and yet the lonesomeness of a large hall with a small audience may be avoided on others, is quite admirable.

With the approval of the executor of the will of Mrs. Hosack, this assembly-hall and the adjoining banqueting-hall are to be the memorial of Dr. Alexander Hosack, and will be known as the

HOSACK HALL.

The half-story above the first enables a height of 26 feet to be gained for the Hosack Hall in the rear, while in front a meeting-room of 30 x 43, and a reading-room or committee-room of 25 x 28 feet are secured. On the level of and in the rear of the larger room, is a logia or gallery 43 feet long, overlooking the assembly-hall, which considerably increases the space for an audience, and provides a place for manipulating a magic lantern when needed to illustrate a lecture.

Arriving at the second floor, a door opposite to the staircase gives admission to the public room of the library, 37 by 43, and 23 feet high. It is this room to

which the public will be admitted, and it will possess all the essential characteristics of a library. Cases arranged in alcoves will extend to about half the height of the room. In this room the librarian and his assistants will have their desks. It is the intention to place in the cases of this room books of reference or such as are in current demand, or of decorative character, and, perhaps, certain special bequests to serve as memorial alcoves. The great mass of books will be stored in a stock-room in the rear and over the Hosack Hall, this room having a capacity for two hundred and fifty thousand volumes. A private room for the librarian, and a strong room for valuable papers are connected with the stock-room, and adjoining the reference library is a reading-room 25 by 28, connecting with corresponding rooms above and below it by a special staircase. These three rooms are for the accommodation of current medical periodicals. On this floor is a detached study-room, 16 by 17 feet, and a commodious toilet-room. The toilet-room for the accommodation of the first floor, it should have been stated, being in the basement. The half-story above the second is mainly occupied by the upper part of the reference library and stock-room, but space is also found for the upper one of the three journal-rooms, 25 by 28; another study-room, 16 by 17; a toilet-room, and small rooms for the storage of duplicate books, etc.

The third story, fourteen feet in height, has four meeting-rooms for sections of the Academy, or other small gatherings. They vary somewhat in size, the smallest being 27 by 28, and the largest 33 by 37. They are all provided with ante-rooms and rooms for storage of apparatus and pathological specimens, laboratory work, etc., and one will be provided with a northern skylight arranged for photographic work, where fellows of the Academy, whose offices do not permit of such work, can secure a good light for photographing interesting cases. These small rooms vary in size from 11 by 12 to 9.6 by 21. A toilet-room also communicates with the hallway on this floor.

The fourth story, besides having a room 28 by 28 feet which can be used as a meeting-room, museum, or laboratory, has an area of 37 by 43 feet arranged for the apartments of the resident librarian. These with the staircase-hall, will cover but about half the area of the building. The remainder will be a level, open deck, covered with flat tiles and surrounded by an iron railing, which can be used as an open-air promenade.

The gable contains, besides the main trunk into which will open the ventilating flues, space which can be used, if needed, for storage of furniture, rooms for attendants, etc.

The basement is utilized for a large kitchen under the banqueting-hall; an air-space under the assembly-hall from which warm or cool air can be forced by a revolving fan into all parts of the building; a room for unpacking books; a room for fuel, and, in the sidewalk vault, the boilers and necessary pumps and other engines.

This is, in brief, an account of the building which the Academy expects to occupy about October, 1890. Compared with the room over the office of a coal-yard of forty years ago, it will be most sumptuous. When completed it will afford accommodations for a medical library of the first magnitude, a meeting-place for medical and other scientific bodies second to none in this country, and rooms suited to the prosecution of scientific study which will rival the laboratories of any of our wealthy universities. In the event of an International Exhibition being held in New York in 1892, it will become the headquarters for all visiting physicians, and by its existence contribute greatly to the credit which, it is to be hoped, this city will acquire for the liberal encouragement of the arts and sciences. Physicians will be proud to be enrolled among the fellows. The existence of its free public library will bring the profession into more intimate relations with the sympathies of the community in general, and endowment of the library and of lectureships will offer to liberal patrons ways for expending money which has heretofore been devoted to objects less closely allied to the public welfare.

# Society Reports.

## MEDICAL SOCIETY OF VIRGINIA.

*Twentieth Annual Session, held in Roanoke, Va., September 3, 4, and 5, 1889.*

(Special Report for THE MEDICAL RECORD.)

### TUESDAY, SEPTEMBER 3D—FIRST DAY.

THE session was called to order by the President, Dr. E. W. Row, of Orange, Va. After prayer, and the address of welcome, by Dr. A. Z. Koiner, of Roanoke,

DR. THOMAS J. MOORE, of Richmond, delivered the "Annual Address to the Public and Profession," selecting as his subject,

MAN AND HIS DEVELOPMENT.

The first meeting was open to the public, and the Opera House was well filled with ladies and gentlemen.

The report of the Committee on Nominations (Dr. W. D. Turner, of Fergusson's Wharf, chairman), recommended about fifty-five applicants for fellowship, each of whom was elected a fellow of the Society.

The report of the Recording Secretary, Dr. Landon B. Edwards, of Richmond, stated that fifteen fellows had died during the year, and six had tendered their resignations of fellowship—having either removed from the State or discontinued practice—leaving a total membership of about seven hundred and thirty-five.

The reports of the Executive Committee (Dr. W. W. Parker, of Richmond, chairman), and of the Publishing Committee (Dr. C. W. P. Brock, of Richmond, Va., chairman), were also presented.

### WEDNESDAY, SEPTEMBER 4TH—SECOND DAY.

DR. JOHN A. WYETH, of New York City, read, by invitation, a paper on

THE STATUS OF COCAINE IN SURGERY,

referring first to the dangers of the drug, due to the idiosyncrasies of patients. Its dosage is uncertain in different individuals, and even in the same persons at different times. As a rule, begin with the minimum dose, and gradually increase—always carefully watching the pulse, face, respirations, and pupils. In small doses it is a cardiac and respiratory stimulant; but in large doses it arrests the heart in diastole and paralyzes the respiratory muscles. It is not applicable to children under ten or twelve years of age. In adults, he has several times witnessed pallor of the face and fainting, but has thought these the results mostly of the patients being overcome by the sight of blood in operations, etc. Exhilaration is not uncommon—amounting to boisterousness in some. He has seen convulsive movements followed by opisthotonos in one case. In another, a decided convulsion occurred fourteen hours after the gradual injection of thirty minims of a four per cent. solution. Systemic absorption of the drug, when not applied about the eye or its direct connections, is proven by the dilatation of the pupil. His usual formula for hypodermic administration is approximatively a four per cent. solution (cocaine muriate, 3 j., boracic acid, gr. iij, and distilled water, ʒ j.). Always use water free of lime for cocaine solutions.

When operating on the extremities, with cocaine as the anæsthetic, the speaker first applies an Esmarch bandage. For amputation of the fingers, it is best to arrest the circulation by simply using a rubber tube or band applied around the finger, as high up toward the metacarpal junction as possible. As direct injections (along the line of proposed incision) retard union and repair of wounds by first intention, it is best to employ the indirect method (injections near the nerves at the base of the finger) when possible, although this latter requires a larger quantity of

cocaine and a little longer time for anæsthesia. The ligature at the base of the finger being in position to tighten, just before tightening it insert the smallest hypodermic needle through the skin, on the lateral aspect of the dorsum of the digit, about an inch from, and on the distal side of, the ligature. Inject two minims; push the needle a quarter of an inch farther, and inject two more minims, and thus proceed until at length the needle-point rests just beneath the skin, on the plantar aspect of the finger, when two minims more are injected. The operation is immediately repeated on the other half of the finger—the entire operation not lasting longer than half a minute. A smarting, burning pain is felt as the fluid enters the tissues. At once tighten the ligatures around the base of the finger, thus holding the solution at a standstill for absorption, which may be hastened by massage. Insensibility sufficient for amputation of the last phalanx occurs in about two minutes. The total quantity of solution that may be used varies from fifteen to thirty minims. Of course, some of the cocaine is eliminated in the hemorrhage of the operation itself. The amputation being finished, loosen the ligature for only a minute, which restores the circulation, when some more of the cocaine is washed out by the renewed hemorrhage; but a good deal of it is carried back into the system by the venous return of blood. Tighten the rubber again for two or three minutes, make the necessary sutures, and apply the dressing. Then for a minute or so again loosen the tourniquet, and again tighten, and thus repeat two or three times, to prevent the heart and nerves from being overwhelmed by the sudden taking up into the system of all the cocaine that was put into the finger.

THE ADVANTAGES OF THE DIRECT METHOD

are: Rapidity of anæsthesia, the smaller quantity of cocaine used, escape of much of the solution through the wound of incision. This method is preferable when the necessary anæsthesia can be obtained by not more than a drachm of a four per cent. solution, as, for instance, in incising felons, removing diseased nails, foreign bodies under the skin, etc.

In operations upon the trunk, the immediate absorption of the solution renders greater precaution necessary. For instance, if a fatty tumor is to be removed, insert the needle in the deeper layers of the skin (not subcutaneous fat) along the line of proposed incision, and inject a half-minim to one minim; advance the needle one-fourth inch and repeat the injection, and so on, as far as the needle will reach from the original puncture. The anæsthesia is evidenced by the pallor of the overlying cuticle. Divide the skin through the anæsthetized line, and dissect laterally—usually about an inch—until pain is felt. Then inject a half-minim or more at all sensitive points to be cut.

In eye surgery the value of cocaine is well known. In the buccal cavity its applicability has even a wider range. It anæsthetizes sufficiently to remove tumors of not more than one inch. Small epitheliomata and suspicious ulcers are painlessly removed from the tongue when from five to twenty minims of solution are injected around and beneath their bases. Dr. Wyeth has twice dissected out ranulæ painlessly under cocaine anæsthesia. Complete clefts of the soft palate in the adult can be painlessly closed by applying the solution with a brush to the mucous surfaces which are to be "freshened up." Cocaine is in every-day use for operations about the nose, nasopharynx, and larynx.

For internal urethrotomy, regardless of location, he now rarely employs general anæsthesia. After disinfecting the urethra with boracic acid solution (gr. x. to ℥ j.), inject from ℥ j. to ℥ ij. of a four per cent. solution of cocaine with the ordinary P-syringe. In a minute or so, let all of the cocaine solution run out that will do so. If the urethrotomy is to be in the membranous portion, pass Otis' long curved tube into that part, and inject from twenty to thirty minims. When the time comes, about the third day after the operation, for the introduction of the sound, be careful not to overdistend the canal with the preliminary solution of cocaine; about a drachm is enough. Cocaine anæsthesia is also very useful for numerous bladder troubles, examinations, etc.

Circumcision in adults no longer requires general narcosis. Constrict the penis near the pubes, pull forward the prepuce, and enter the hypodermic needle at the free border in the middle line on top, *between* the mucous and cutaneous layers. Then carry the point of the needle as far back as the proposed line of section, and inject one minim of the cocaine solution. Withdraw the needle half-way, and carry it forward again to the right and left, and force out a minim for every quarter-inch of the proposed section. As the frænum is very sensitive, inject two or three minims here.

In Levis's operation for hydrocele, cocainize the point where the trocar is to enter. If the hydrocele is small, Volkman's operation may be done under cocaine.

But in the open operation for varicocele, cocaine is not sufficient; nor is it sufficient for external urethrotomy, cystotomy, hernia, etc.

But small hæmorrhoids may be injected with the cocaine solution, and almost painlessly removed. Cocaine is also sufficient for incising anal and rectal fissures and ulcers; also for slitting up single and superficial anal and rectal fistulæ.

Dr. Hunter McGuire, of Richmond, did not think Dr. Wyeth's paper dwelt sufficiently on the dangers of cocaine. It is a very tricky agent. He had, however, used it nearly every day for the past five years, because it is just the anæsthetic often wanted when it acts well. While he has had no fatal case from its use, he has yet come very near killing one or two patients with it, so uncertain is its paralyzing effect in some cases—which cases cannot be foretold. He had read in one of his journals that Dr. Sims had injected a few minims of a twenty per cent. solution into the male urethra, and in twenty minutes, he thinks it was, his patient was dead. Dr. McGuire said he had cocainized a great many children without observing in any case the very serious effects referred to by Dr. Wyeth; in fact, he had come to the conclusion that children stand cocaine anæsthesia as they do chloroform—very well. But there are objections to cocaine, which belong to the experimental therapeutist to remove if he can. Undoubtedly it interferes with the repair of wounds by first intention. During the session of this Society in Richmond, two years ago, a distinguished author, then residing in New York, affirmed that there was no such thing as a "cocaine habit," in the sense in which the term "habit" is applied to the "whiskey habit," the "morphia habit," etc. But Dr. McGuire is certain he has seen cases of "cocaine habit."

Dr. Wyeth remarked, in conclusion, that he indorsed what Dr. McGuire had just said. The dangers of the indiscriminate use of cocaine are very great. His paper did not intend to imply the idea that danger in the use of cocaine with children was in the drug itself; but that it was not suited to them because of the difficulty in properly administering repeated hypodermic injections to children under any circumstances, and the peculiar sensation of loss of feeling in the part, which frightens them.

Dr. E. W. Row then delivered the President's address, his subject being

MEDICAL REFORMS,

with special applicability to the profession of Virginia.

CROUPOUS PNEUMONIA

was the subject for general discussion.

Dr. B. L. Winston, of Hanover Court House, in opening the discussion, confined his remarks to uncomplicated cases. Diagnosis, if physical signs are resorted to, is easy, though the disease sometimes is not recognized with such examination. Pain is probably never present, unless pleurisy complicates the pneumonia. Rusty-colored

sputa, although pathognomonic, according to his experience, by no means occur in the majority of cases; and yet text-book authors would lead us to expect this in every instance. The causes of the diseases are either specific, exciting, or predisposing. The theory of the *specific* origin of pneumonia does not meet with common approval. Yet pneumonia is not a simple inflammation of the lung; this is but an expression of a general disease. The lung inflammation itself deserves no higher rank than the intestinal ulcers of typhoid fever. Croupous pneumonia is not produced by extension of inflammation, although lobular pneumonia is the result of such extension. It is not produced by inhaling irritating gases, nor by traumatism, nor by "cold," as are other inflammations of the air-passages. It is a self-limited disease, and often occurs as an epidemic. The asthmatic tendency cannot be due to the height of the fever, nor to cardiac weakness, nor to the amount of lung consolidated, for the amount invaded is often very small. Besides, the heart-failure in no way corresponds with the severity of the other symptoms. The heart-failure which is the alarming symptom in uncomplicated cases is apparently due to a morbific agent acting on the nerve-centres. But the exact cause of croupous pneumonia is a subject for further investigation. The germ theory may or may not be true. The predisposing causes are age, under sixty; the male sex; the negro race; winter and spring seasons; and certain diseases, as typhoid fever. The exciting causes are, in general, such things as tend to lower the vital powers, as exposure to inclement weather, insufficient clothing—especially the neglect of flannel. The disease is more common South than North—being almost unknown in the frigid zone. During the cold months, almost all food is old; thus it is probable that the character of food then taken, while the vital powers are at their lowest, contributes most largely to the development of the disease. As to treatment, almost every drug has been tried, and yet the mortality is second only to that from consumption. Maragliona abstracts from five to ten ounces of blood on the fourth or fifth day, when the heart is on the eve of being overpowered by the pneumonic toxic matter. While venesection may sometimes be required, Dr. Winston does not think the evidence sustains the general adoption of Maragliona's practice. Large blisters are of doubtful propriety, although they do oftentimes relieve pain. Calomel has no place in the treatment of croupous pneumonia. Aconite in the commencement, and quinine from the start to abort the disease, may at times prove useful. But Dr. Winston, as a rule, has gotten the best results when he has used the least medicine. Hot poultices, opium to relieve pain, stimulants when needed, food, hygienic measures, and, above all, skilful nursing, will be all that can be done in uncomplicated cases.

Dr. H. C. Beckett, of Scottsburg, read the next paper, covering much of the ground of the first. He said the specific cause of croupous pneumonia is unknown; no age is exempt, though the disease is very rare in children under five years; occurs mostly in males; in laborers more often than in those who live in-doors, etc. Erysipelas, measles, diphtheria, small-pox, etc., are predisposing causes, as are a previous attack of pneumonia, and traumatism, especially in the old. It is most frequent in the Middle and Southern States. It often prevails as an epidemic in the mountainous regions of the South, and occurs mostly during the first five months of the year. In short, everything that tends to depress vital action predisposes to croupous pneumonia. As to treatment, use stimulants or depressants as required. Bleed, if both lungs are involved so as to leave but little breathing surface. In such cases, the relief is immediate. Large hot poultices over the lungs reduce blood-pressure, while the heat acts as a cardiac stimulant. Aconite is preferable to veratrum when a heart-sedative is needed. Antifibrin is the best antipyretic, and should be followed by quinine, which latter he considers the sheet-anchor in pneumonia—about five grains every four hours until the fever breaks. In the second and third stages, combine ammonium carbonate and digitalis if indicated. The early use of a large dose of calomel is beneficial. Use opium to allay pain and restlessness. Expectorants have no place in the treatment of pneumonia. Blisters at the beginning of the third stage hasten resolution. Alcohol is essential as food and a stimulant. Some believe pneumonia to be contagious, and that the period of incubation is four days; but Dr. Beckett does not believe it is contagious.

Dr. Lewis G. Pedigo, of Roanoke, read a paper on

SEDATIVE DOSES OF CALOMEL IN ACUTE CROUPOUS PNEUMONIA.

He reviewed the literature relating to the use of the so-called heroic or sedative doses of this drug in various acute diseases, set forth in systematic order the various effects of such doses on the secretions, the temperature, and the nervous system, and argued that these effects answer to the indications in pneumonia. The doses referred to in this paper range from thirty grains upward. The favorite method of administration is to sprinkle dry on the tongue.

Dr. Bedford Brown, of Alexandria, gave a résumé of his personal experience in the

TREATMENT OF CROUPOUS PNEUMONIA

during a period of forty-one years. During this time he has seen four or five different methods of treatment adopted and practised, and finally discarded. First, the depletory. At first it was used in every case, then in only certain cases, and finally it was entirely discarded. Then came the mercurial, in which calomel in small doses, with Dover's powder, blistering, and mercurial inunction, was used until ptyalism occurred. The great majority of cases recovered under this treatment. Then followed the sedative treatment—veratrum, aconite, and ultimately digitalis. The sedative treatment of Norwood gave birth to all of our subsequent ideas of sedation. This was an advance on the pure depletory treatment, and resulted in real good. Then, again, came the stimulant treatment. This was a still further advance, and has brought more and better points than any other single treatment. This also may be modified and combined with elements of the other treatments with advantage. Dr. Brown has not derived benefit from the pure antipyretic treatment. He has in former years seen much of the epidemic form—a typhoid pneumonia—the tendency to collapse in which was constant and great. In this form he has used large quantities of whiskey (a quart per diem), carbonate of ammonia, tincture of nux vomica, and chloroform, internally. In this form he has also used, in connection with stimulants, liquor ammoniæ acetatis, tincture of nux vomica, and tincture of chloride of iron with benefit. Dr. Brown does not think, from this long experience, that adherence to any one single routine treatment exclusively will give as good results as the mixed—combining some of the good portions of all, but never forgetting stimulants and nourishment. He has seen cases of pneumonia with slight fever, slow pulse, and moderately excited respiration recover without medication.

Dr. J. H. Neff, of Harrisonburg, believed that acute croupous or lobar pneumonia is a general disease due to a specific poison. This theory has been ably presented for some years, and much can be said for and against it. But each year's experience has strengthened his opinion in its favor. The future organic chemists and bacteriologists must prove whether it be a chemical poison or an organized germ. Believing that it is a general disease, due to a specific cause, for which there is no specific medicine capable of aborting its course, the treatment must be determined by the nature of the disease in each individual constitution. He has never bled or given a dose of aconite or veratrum viride, nor used mercury except to give occasionally an ordinary dose of calomel in the beginning. Many cases will recover without medi-

cine if properly nursed; this was observed and recorded more than twenty-five years ago. He has seen cases of double pneumonia with scarcely a bad symptom. The area of lung involved does not always determine the gravity of the disease. He gives opium or morphia to allay pain, lessen shock, produce sleep, etc. He regards quinine as the safest antipyretic; besides, it has special virtues in lessening the gravity of all local inflammations. He has never seen it produce collapse, and hence prefers it to other arterial sedatives. If not needed as an antipyretic, it may be of benefit in small tonic doses. He gives antipyrin to children; and if he has any routine treatment, it is to envelop their chests with an oil-silk jacket, lined with soft, fine flannel. Digitalis, alcohol, ammonia, and chloral have all, in their places, been of much service.

Dr. J. G. Wiltshire, of Baltimore, Md., said that, studying the subject of croupous pneumonia after Lépine, Sévestre, and Charcot, one must accept the theory that it finds its origin in a specific pathogenetic germ; yet it cannot be denied that there are certain meteorological conditions that stand in a strong causative relation to its production, it occurring more frequently in a low temperature —one acting as a specific, the other as an exciting cause. We are constantly exposed to the invasion of the pneumococci, but, for the want of the necessary conditions to render the mucous membrane of the lung a suitable soil for their culture and growth, it is able to resist them for a time; only to yield when such exciting causes as cold and traumatism supplement the specific influence of the germs. Apropos of the theory that the pneumococci have other habitats than the lungs, he called attention to the study of Sévestre of an epidemic of broncho-pneumonia complicating cholera infantum and other enteric troubles, in which he found the microbes of pneumonia in the intestinal tract, whence they were carried to the lung by the lymph-channels. The treatment of croupous pneumonia calls for heart-sedatives, and heat and moisture, in the form of hot cloths. These, if used in the first stage, may abort the disease. Should it, however, pass into the stage of red hepatization, a supporting and stimulating plan should take the place of the sedative one. Watch the temperature and heart as closely as the powers of the patient. Alcohol is important in the second and third stages. Quinine and antipyrin, when used together, are the best antipyretics. They not only reduce the temperature, but preserve the power of the heart. Carbonate of ammonia does the twofold work of aiding in liquefying and expectorating the fibrinous deposit, and keeping the heart's force up.

Dr. Henry M. Paterson, of Staunton, said that if this is a specific disease, the treatment given has certainly been at variance with such an idea. He does not believe that it is a simple hyperæmia of the lungs. The gravity of the attack depends on the amount of exudation. How to remove the engorgement is the question. This is the time to abort the disease, if such a thing is ever possible. His present success with the lancet is as great as it was when he began practice in 1851, and compares most favorably with the results of other plans of practice of to-day. As a food and stimulant, he gives alcohol during the second stage in almost every case. He has also had some remarkably satisfactory experience with ergot.

Dr. Henry V. Gray, of Roanoke, also discussed the same subject.

### ELECTION OF OFFICERS.

The election of officers was then held, with the following result: Dr. Oscar Wiley, of Salem, *President*. Drs. J. M. Estill, of Tazewell Court Houre; Alfred C. Palmer, of Norfolk; and Casper C. Henckel, of New Market, *Vice-Presidents*. Dr. Landon B. Edwards, of Richmond, *Recording Secretary*. Dr. J. F. Winn, of Richmond, *Corresponding Secretary*. Dr. Richard T. Styll, of Hollins, Va., *Treasurer*. Dr. John S. Apperson, of Glade Spring, was elected to deliver the Address to the Public and Profession during the session of 1890, and Dr. C. T. Lewis, of Clifton Forge, was selected as the Leader of the Discussion of the selected subject for 1890.

### THE TREATMENT OF THE SUMMER DIARRHŒA OF CHILDREN.

Drs. R. F. Young, of Love's Mill, and P. B. Green, of Wytheville, were nominated for commission as Members of the Medical Examining Board of Virginia, to fill vacancies occasioned by two resignations.

Rockbridge Alum Springs was selected as the place for the Annual Session of 1890, some day between August 25th and September 5th, as the Executive Committee may hereafter determine.

Dr. E. T. Brady, of the Southwestern Lunatic Asylum at Marion, read a paper entitled

### MENTAL ACTION—MATERIAL ACTION.

The doctor stated that he would treat the title as a fact, considering it established by the following three propositions, viz.:

1. That mental impressions involuntarily originate physical action, and that material impressions give rise to this involuntary mental action.

2. That loss of cerebral substance is followed by loss of physical or expressional function, and that disuse of mental function is followed by a corresponding atrophy of cerebral substance.

3. That abnormalities of organic function have as their sequence abnormal ideation.

He devoted his paper to the support of these propositions by arguments based upon normal and abnormal phenomena, and cited records, clinical and post-mortem, of several interesting cases illustrative of his subject.

Dr. William F. Cooper, of Woodville, presented the

### REPORT ON MATERIA MEDICA AND THERAPEUTICS.

From the phenol group, comes *Phenacetine*, a white, glossy, crystalline, tasteless powder, freely soluble in alcohol, less so in glycerine, and still less so in water. Therapeutic attention was called to it in 1887. It is a non-toxic, reliable antipyretic and antineuralgic. The usual dose of seven and one-half grains lowers the temperature from 1.8° to 3.6° F., for hours. It is best given in powders or soluble pills. *Sulphonal* promptly causes natural sleep, in from a half-hour to two hours, of several hours' duration, in doses of fifteen to forty-five grains. It does not act unfavorably upon the heart, respiration, temperature, or digestion. It creates no desire to increase the dose. It is given in wafer, or it may be dissolved in soup or tea. *Amylene hydrate*, an isomer of amylic alcohol, is physiologically ranked between chloral and paraldehyde. It is a colorless, slightly oily liquid, boils at 102.5° C.; sp. gr. o. 81. Its odor resembles that of paraldehyde, with a faint suggestion of camphor. It feels warm in the mouth, and has a hot aromatic taste. It is freely soluble in alcohol, but requires eight parts of water. It is given with extract of licorice, or in red wine and sugar. In doses of from fifty to seventy-five grains, it causes neither nausea, headache, indigestion, nor other unpleasant after-effect; but more frequently than other hypnotics it induces refreshing sleep. *Methylal* is a new hypnotic, with sweet taste, ethereal odor; is soluble in water, rapidly eliminated, and leaves no ill effects. Dose three to five grammes. *Salufer* (neutral sodium silicofluoride), a white inodorous compound, requiring ℥ j. water to dissolve gr. ijss., is a powerful, unirritating surgical antiseptic. For ordinary uses a grain is dissolved in an ounce of water, to syringe out cavities, etc. It corrodes steel, but does not affect sponges. *Guaiacol*, an ether derived from beech-wood creosote, is a colorless liquid, of aromatic odor, slightly soluble in water, but readily so in alcohol and fixed oils. It is used, by inhalations or in doses of a half to one minim several times daily, in consumption. The solution should be kept in colored bottles.

(To be continued.)

## NEW YORK STATE MEDICAL ASSOCIATION.

*Sixth Annual Meeting, held at the Hotel Brunswick, New York, September, 25, 26, and 27, 1889.*

WILLIAM T. LUSK, M.D., OF NEW YORK, PRESIDENT, IN THE CHAIR.

FIRST DAY, WEDNESDAY, SEPTEMBER 25TH—MORNING SESSION.

DR. GEORGE E. FELL, of Buffalo, read the first scientific paper, entitled

### PARTIAL INVERSION OF THE UTERUS,

in which he related the history of a case occurring in a multipara, in whom, eight hours after normal delivery, he was sent for hastily and found the patient in high fever, with anxious countenance, great pain in the pelvis, and partial collapse. The uterus could not be felt above the pubes. The hand in the vagina revealed the fundus uteri low down, the left cornua being most inverted. He placed the patient in the left latero-dorsal position, and made uterine irrigation with hot water while making manual pressure. The organ was wholly and easily replaced in about five minutes. It was necessary to give morphine to quiet the after-pains. There was no recurrence of the partial inversion. Dr. Fell attributed the accident in this case to the fact that in her first confinement she had been delivered by forceps, and the uterus forcibly drawn entirely out of the pelvis.

DR. MARCY, of Boston, thought partial inversion after delivery was more common than had been supposed. An article had recently appeared in which ten cases were given. The etiology was obscure. The cause to which it had been attributed in Dr. Fell's case was very instructive.

DR. FELL also read a brief paper entitled

### LATERO-DORSAL POSITION IN VAGINAL IRRIGATION.

His reason for describing the method was its superiority over others, and the fact that, as far as he was informed, it was new. An ordinary table, sofa, or bed could be used, the right side being covered with oil-cloth raised in folds to carry the water into a bowl at the bedside. The patient was then placed on the oil-cloth, the buttocks very slightly over the edge of the bed, lying on the left side, the limbs flexed. Irrigation in this position allowed the water to pass over the gluteal region into the bowl at the bedside, and could be carried out with ease and success.

DR. W. H. ROBB read a paper entitled

### PELVIC CELLULITIS IN WOMEN.

The first part of the paper quoted views, *pro* and *con*, on the existence of pelvic cellulitis. The author thought there was no reason to suppose inflammation might not exist in the pelvic tissues of the pelvis as well as elsewhere. It might be simple or complicated. He thought the inflammation should receive the name pelvic cellulitis when the cellular tissue was principally involved. He was unable to account for the fact that in different patients the three stages of the disease varied much in duration. The first stage was that of congestion, which might end in resolution. The second was that of effusion, and in some cases was of long duration, and might terminate in resolution or go on to the formation of pus. In the way of treatment, during the acute stage, he found veratrum viride an excellent drug for controlling the temperature and pulse. He also used sulphate of morphine hypodermically. Recognizing infection in the etiology of many cases, he made vaginal, sometimes uterine, irrigation with a solution of carbolic acid, and introduced iodoform. A flaxseed poultice was applied over the abdomen. When pus formed it should be evacuated at once. To reach it, laparotomy might be necessary.

DR. MARCY called attention to the fact that while the author had presented the claims of pelvic cellulitis to being classified as an independent affection, yet he had admitted that its origin was likely to be infection from without; in other words, that it was a bacterial inflammation, whether the bacteria gained entrance through the uterus and tubes or other channel. This fact had an important bearing on treatment. The earlier one was able to remove the direct factor in the production of the disease the more likely would the patient's life be spared.

DR. E. M. MOORE spoke of the mode in which pelvic abscesses should be evacuated. He had employed both incision and drainage, and aspiration, and expressed preference for the latter, as less likely to be followed by certain symptoms attending sudden and complete emptying of pus-cavities by the knife. He saw no reason why pelvic connective tissue might not be the seat of inflammation just as might connective tissue and all tissues elsewhere in the body.

DR. E. D. FERGUSON thought unfavorable symptoms were no more likely to follow incision than aspiration unless infectious matter were introduced. The aspiration should not be employed unless one knew just what tissues the needle had to pass through to reach the pus.

DR. CRONYN accepted Dr. Moore's views regarding the value of the aspirator, and expressed preference for opium to morphine, aided by quinine; opium removed the cause of the fever, while veratrum removed the symptom only. Indeed it had not been efficient in his hands even for this purpose.

DR. ROBB related a case in which the aspirator-needle had been introduced in three different directions. No pus was found. An abscess afterward formed, however, which he believed had been excited by the punctures.

The objection to opium was that the stomach rejected it in many cases. Veratrum, in reducing the pulse, tended also to cure the inflammation by lessening the amount of blood pumped through the congested parts by the over-acting heart.

DR. C. S. WOOD, of New York, reported a case of

### LAPAROTOMY FOR RUPTURED PYO-SALPINX—ERROR IN DIAGNOSIS—RECOVERY.

The case well illustrated the difficulties sometimes encountered in diagnosis. The patient was an unmarried woman, aged twenty-eight, who had been in good health, except at times pains were present in the lower part of the abdomen. In May last Dr. Wood was called, and found her suffering from abdominal pain, slight fever, and gastric disturbance. A cathartic was administered, which acted the following day. The pain became greater in the pelvic region, especially in the region of the cæcum, where was present indistinct hardness. The tumor in this region increased in size, and Dr. Wood became convinced the case was one of perityphlitic abscess. She was getting along well until after some days she was awakened in the night by "sickness of the stomach," had a severe chill, and partial collapse. The induration in the iliac region was found to be softer and less prominent. Projective vomiting of watery fluid took place when she was turned on her side for examination. The temperature was 103.5° F., pulse 140. Being satisfied of rupture of a perityphlitic abscess, Dr. Wylie was called in consultation, laparotomy was performed, and they were surprised to find no evidence of inflammation or tumor in the immediate region of the cæcum; instead, there was an effusion of lymph over a large surface, matting together of pelvic viscera, and rupture of a pyo-salpinx on the right side, which had been mistaken for a perityphlitic abscess. The sac and ovary were removed. The ovary on the left side being cystic, it was also removed. The patient recovered within four weeks. He afterward learned that she had, five years previously, brought on an abortion, which might account for the attacks of pelvic pain.

DR. EDIBOHLS mentioned two diagnostic points in distinguishing between perityphlitic abscess and pyo-salpinx. In the former the tumor lay midway beneath a line drawn from the anterior superior spinous process of the ilium

to the umbilicus. The second point was that during the first six or seven days, or until the tumor reached a large size, a perityphlitic abscess could not be felt by the two fingers introduced within the vagina, or one introduced into the vagina and the other into the rectum, whereas a pyo-salpinx could invariably be felt in that manner.

---

### Afternoon Session.

#### THE PRESIDENT'S ADDRESS.

Dr. Lusk read his address, which opened the

#### DISCUSSION ON TUBAL PREGNANCY,

including relative infrequency of other forms of extra-uterine pregnancy; the interstitial, intra-ligamentous, and pedicled forms; the physiology, pathology, and diagnosis; clinical history and objective signs; the possibility of early diagnosis prior to rupture; and treatment, both prior to and after rupture, and after viability of the child.

He first gave the histories of two illustrative cases which occurred in his practice last winter. The first was that of a woman whom he was called to see in consultation on November 19, 1888. She was suffering from severe shock and intense anæmia. On the 11th she had been seized with cramps, nausea, and at times vomiting. When he was sent for, on the 19th, she had suddenly become exsanguinated, suffered from increased pain in the pelvic region, was excessively anæmic and vomited constantly; the pulse was 140. The pains had ceased on his arrival. The uterus was found pressed somewhat to the left; on the other side, and posteriorly, was an irregular soft mass, which obscured palpation of the uterine appendages. The diagnosis was rupture of tubal pregnancy, with intra-peritoneal hemorrhage. Laparotomy was recommended, and the next day, in spite of the fact that the patient was feeling comfortable, she was transferred to the hospital for operation. She arrived in a state of prostration, but was revived by stimulants during the night, and operated upon the next morning. When the peritoneum was incised a stream of dark blood, probably not less than two quarts, gushed out. The pelvic cavity was filled with clots, which he removed. The hemorrhage seemed to proceed from a sac in the broad ligament, which had ruptured into the peritoneal cavity. A silk ligature was made to include the tube, sac, and ovary, the ligated mass was removed by thermo-cautery, and the pedicle was dropped. The other tube and ovary were perfectly healthy. The abdominal cavity was irrigated. The operation lasted about forty-five minutes. In the afternoon, while vomiting, a large amount of fluid was forced through the drainage-tube, but he subsequently concluded that this was not due to secondary hemorrhage, of which he at first had fears. The patient made a good recovery. The embryo corresponded to about the sixth week. Reviewing the case, he said the first hæmatoma had formed between the folds of the broad ligament. The distention caused by effused blood had converted the posterior layer at the point of pressure into a sac, in which, at the time of operation, an opening was found about the size of a man's thumb. It appeared, then, that hemorrhage into the tube occurred first, and corresponded to the symptoms of the 11th. The thinning of the tubal walls was such that the non-occurrence of rupture of the intra-peritoneal wall at that time seemed almost a miracle. If the rupture of the tube was coincident with the occurrence of the first hemorrhage, separation of the folds of the broad ligament and formation of a pouch probably took place gradually. Sudden anæmia and prolonged unconsciousness on the 19th marked rupture of the sac and pouring of blood into the peritoneal cavity. Subsequent formation of clots in the pelvis served as a temporary check to hemorrhage.

The other case was similar; there was rupture of the sac, laparotomy was performed easily, the ovum was presumably of the fourth week, recovery seemed almost certain, when she suddenly died on the eighth day, of albuminuria. The two cases illustrated the ordinary history of tubal pregnancy. In the one instance the blood made its way between the folds of the broad ligament; in the other, it poured into the peritoneal cavity. Mr. Tait, he said, held that all cases of extra uterine pregnancy were in the beginning tubal. They might become abdominal by rupture; but he regarded the ovarian form as possible. The subject was too new, however, for any scheme to be regarded as final. It was not likely, however, that the ovum was capable of forming a nutritive connection with the peritoneum in the first place. In more advanced stages many cases of assumed abdominal pregnancy had been placed in evidence. They could be divided into two classes: 1, Cases in which the tubes had been reported intact, but in which there was direct communication between the tube on the affected side and the abdominal cavity; 2, cases in which the tubes had been reported intact, and not in communication with the cavity. The author criticised some of the reported cases of this nature. There was little question, he thought, of the occasional occurrence of ovarian pregnancy. Mr. Tait was undoubtedly right in insisting on the importance of chronic forms of salpingitis in the etiology. Tubal pregnancy was associated with the formation of a uterine decidua, which differed in no way from the decidua of uterine pregnancy, except that the three layers were less marked.

Unquestionably, early rupture of tubal pregnancy was the rule. Mr. Tait had not been able to satisfy himself that it was ever delayed beyond the twelfth week. Rupture at the placental site gave rise to hemorrhage, invariably fatal to the fœtus. The same was true, with rare exceptions, when rupture occurred at any point on the peritoneal surface. In most cases in which the pregnancy reached an advanced stage the development of the tube took place principally between the folds of the broad ligament. The support furnished the tubal walls by the gradual unfolding of the ligament hindered rupture. Occasionally pregnancy went on to viability without encroaching on the intra-ligamentous space. The tube then arose above the pelvic brim.

The intra-ligamentous form lay close to the uterus. In others the uterine end of the tube varied greatly in length. In the so-called pedicled form the uterus was crowded to one side or retroverted; the uterine end of the tube was usually long and thickened. The relations of the sac were often obscure.

The interstitial variety was that in which the ovum developed in the uterine portion of the tube. In twenty-six cases collected by Hégar all ruptured before the sixth month, Tait said before the fifth month.

A burning question connected with tubal pregnancy was that of diagnosis. Mr. Tait assumed a skeptical attitude in relation to the claims of some men to ability to make a certain diagnosis in all cases. The subjective symptoms and physical signs previous to an operation might prove deceptive. The use of the uterine sound in diagnosis had been the cause of many needless abortions. Moreover, intra-uterine pregnancy not infrequently persisted after the cavity had presumably been shown to be empty by one or more passages of the sound.

Main reliance must be placed on local symptoms and changes collectively. In the intra-ligamentous form the chances of error in diagnosis were slight. There was distinctive evidence of a rapidly growing tumor, early fluctuation; bimanual palpation made it possible to determine whether the tumor was independent of the uterus. Dr. Lusk thought not much reliance could be placed upon uterine changes during the early months. Grandin attached importance to the presence of rhythmic contractions in the uterus after the third month of uterine pregnancy, as distinguishing that form from extra-uterine and certain other conditions. More clinical observation was needed on that point. In his own experience lateral flexion of the uterus simulated ectopic gestation to a surprising degree. There was a considerable number of cases in which diagnosis could scarcely be doubted.

Regarding the value of electricity, he had had two cases

in which it was used, the diagnosis having been confirmed by Dr. Thomas. In both the tumor shrivelled, the other signs of pregnancy disappeared. The only argument against the method, when used properly, was its liability to cause rupture, and the retained ovum to undergo suppuration. But these possibilities were very slight. The method was only applicable during the first three months. No one in this country advocated electro-puncture. Electricity did not stand in the way of subsequent laparotomy. It was safer in the hands of the inexperienced than was laparotomy.

Dr. William Goodell, of Philadelphia, opened the discussion. With reference to the causation of extra-uterine pregnancy, he did not think we were at present in a position to accept wholly the views of Mr. Tait. There were strong arguments in their favor, and also against them. He did know that fibroid tumors had been, or seemed to have been, the cause of extra-uterine pregnancy. Distortion of the womb or tubes through adhesions was undoubtedly a cause. This statement was supported by the fact that in many cases the extra-uterine pregnancy followed a long period of sterility after a first pregnancy or pregnancies. He believed the trouble was much more common than had been recognized. While there was reason for some doubt, yet he was disposed to accept Mr. Tait's view that originally the pregnancy was always tubal, and secondarily might become intra-ligamentous and ventral. In the course of its development the intra-ligamentous form of extra-uterine pregnancy behaved like an intra-ligamentous cyst, splitting up the layers of the peritoneum on the posterior surface of the womb, on the bladder, its reflection from the bladder to the abdominal wall, etc. The same course of development accounted for the occurrence of fecal fistula in some cases.

With regard to symptomatology, there was usually suppression of the menses, which might last two months before the physician was consulted, or after two weeks it might be followed by dribbling of blood. Colicky pains were usually present, and in connection with suppressed menstruation led him to suspect extra-uterine pregnancy, especially if inflammation were absent A symptom on which he was disposed to lay some stress was the fact that in early pregnancy there was usually increased frequency of micturition, especially at night. This seemed to be more marked in extra-uterine pregnancy. The chief objective symptom was displacement of the uterus by the tumor. Often, however, an operation was justifiable although an absolute diagnosis could not be made.

In treatment he agreed with Dr. Lusk, that the aspirator should not be used. He had been surprised to read of the number of cases of cure by injection of morphine, yet he would not feel himself justified in resorting to it. He would not employ electricity. There were only two circumstances, he thought, which justified it, (1) where the patient peremptorily objected to an operation; (2) where the physician had not sufficient experience and skill to do laparotomy. If the child were viable, say at the seventh month, he would be disposed to wait until the eighth month. He had met with one case in which there was twin pregnancy, the one intra-uterine, the other extra-uterine.

Dr. Goodell related the causes of extra-uterine pregnancy which had come under his observation; in at least two the patients refused an operation, and died; in some the diagnosis had not been made by others; in some it was more or less conjectural. In his last four cases, in three of which the diagnosis was made before the operation, recovery followed laparotomy.

Dr. Marcy, of Boston, related two cases in which the autopsy showed extra-uterine pregnancy, and conclusively, as he thought, of the ventral form from the first. The fœtus was located quite above the brim, quite central, attached to the intestines, etc. He opposed the use of electricity.

Dr. J. E. Janvrin emphasized the diagnostic value of colicky pains, when taken in connection with other signs of extra-uterine pregnancy. He attributed the pain to distention of the peritoneal covering of the tumor. He advocated the knife.

Dr. Lusk thought colicky pains were so frequently associated with other conditions that they could not be regarded as of great value.

---

Evening Session.

Dr. E. J. C. Minard read a paper entitled "A Word in Favor of Free Dispensary and Free Hospital Work," which had been read on a previous occasion.

Dr. George E. Fell read a brief paper entitled

THE MICROSCOPE IN DIAGNOSIS; PERSONAL OBSERVATIONS.

The microscope revealed the intimate structure of tissues, and illustrated the morphological changes producing pathological conditions; yet the range of the instrument in diagnosis was somewhat limited.

The following letter, received from Dr. U. C. Lynde, was one of several showing its value in diagnosis and prognosis of pulmonary affections: "In the summer of 1884 I was attending two patients, aged about forty; both had night-sweats, hectic fever, emaciation, rapid pulse, etc., physical signs alike; and so similar were their symptoms that my prognosis was the same for both—unfavorable, my diagnosis being pulmonary tuberculosis. Sputa were sent to your office for microscopical examination, you having no knowledge whence the sputa came. The sputum of one was found loaded with bacilli, while that of the other contained none. The former died inside four months, while the latter recovered and is now well."

In some cases the result of the examination had been negative, but more frequently it was of a positive nature.

Dr. Fell also read a paper entitled

FORCED RESPIRATION—ADDITIONAL OBSERVATIONS.

His further experience had been in cases of opium narcosis, and the asphyxia of the newly-born. It went to confirm his former favorable opinion of the method.

He was satisfied the method must in time take the place of artificial respiration.

Dr. Henry F. Risch read a paper entitled

THE RATIONAL DRESSING AND TREATMENT OF THE UMBILICAL CORD AND UMBILICUS.

After mentioning several other methods and their disadvantages, he described that practised some years by himself and Dr. Otto Risch, with great satisfaction. The cord was tied with one or more strands of thick silk "just exactly on neutral ground," or "between what belongs to the child and what does not." Then, after tying the usual second ligature on the cord, it was cut between the two. The jelly of Wharton was then industriously rubbed out, the stump most carefully dried, and either wrapped in scorched linen or muslin, or, better, dressed with powdered charcoal or animal carbon. The navel band should be kept perfectly dry. If the dressing remained dry, it was not changed until the little stump fell off, which usually occurred on the second or third day. The navel thus formed was smaller than after the usual dressing, nor did it ever protrude. The danger of septic poisoning and gangrene was avoided by this method.

Dr. T. D. Crothers, of Hartford, read a paper entitled

ALCOHOLIC PARALYSIS,

which will appear in a future issue of The Record.

Dr. Ferguson mentioned a case in a woman, in whom alcoholic paralysis led to an unusually early and fatal termination. He asked Dr. Crothers if he had seen many such cases, and received an affirmative answer.

Dr. E. M. Moore had listened to the paper with a great deal of pleasure, both because it marked a new departure in medicine, and presented views which had lingered in his own mind many years. Our knowledge of the subject

of alcoholic paralysis had been retarded by the fact that, as a rule, only the immediate effects were looked to, and the cure regarded as perfect as soon as the effects of the debauch had passed away. The paper took the right view, that the effects did not pass immediately away, but that a profound influence was produced, which might never pass away. There would be no difficulty in controlling the class of cases described when the law should recognize them as cases of insanity. They would then be confined, and receive appropriate treatment.

Dr. Carroll wished to hear from Dr. Crothers what he regarded as the intemperate use of alcohols. When the quantity which the person was capable of oxydizing had been exceeded, the alcohol began to produce a paralyzing attack, and in the end led to degeneration.

Dr. Crothers replied that all research went to show that alcohol was a complex body, and it would require centuries of laboratory research to answer the question what could be regarded as the temperate use of alcohol. Clinical observation was at present of more value.

Dr. H. D. Didama next read a paper entitled

### A FEW FADS,

in which he treated humorously and sarcastically of "faded fads," "fading fads," "blooming fads," and "fads in full bloom." Among the first was the "blue-glass fad;" and among the second was the "new elixir fad."

Dr. Alfred L. Carroll being asked to open the discussion, said he thought it might more appropriately be opened by a gynecologist. He ventured to suggest some future fads. For instance, it had been observed that in enteric and malarial fevers, the spleen was enlarged. Removal of the Fallopian tubes had been shown to prevent pyo-salpinx; might not removal of the spleen prevent the development of typhoid fever? Again, an enterprising young surgeon might become notorious and have an income of five thousand a week, based on the fad of extirpating the vermiform appendix of all newly born, and thus removing the cause of many cases of abdominal surgery.

Dr. T. H. Manley read a paper entitled

### SOME OF THE USES OF THE TRANSFIXION LIGATURE.

The author's investigation in this direction had been instigated by a case in which the transfixion ligature saved the life of his patient. While dissecting out tubercularly enlarged glands of the neck, suddenly a large stream of blood gushed out, which he was unable to control by pressure. The common carotid had been opened, and the patient was in imminent danger of exsanguination. Observing a needle with a ligature lying on the table, he hastily passed it under the tissues whence the hemorrhage proceeded, ligated the tissues, and at once the bleeding ceased. The patient was discharged cured after ten days. He then experimented with the transfixion ligature on the cadaver and on dogs, and found that injury to nerves or important parts was not likely to take place in the case of most of the vessels of the extremities, and if antiseptic precautions were observed infection would be avoided. The ligature, of course, was only temporary, to be employed in urgent cases where vessels had been wounded by accident, or in operations in which it was preferable to render the parts bloodless by this method rather than by the Esmarch bandage, etc. He was convinced that the transfixion ligature could be safely and easily applied to any healthy vessel in the external region of the body. Its use being only temporary, injurious results from suppression of function of parts included in the ligature would not be likely to occur; most was to be feared in this respect from its use on the large vessels of the neck, where important nerves might be included. Strict asepsis should exist. He had employed this method while operating for a femoral aneurism, and also in a case of epithelioma of the lip. In the latter instance it was of special value, since it completely controlled hemorrhage, which could not be done in any other way. The method had also been tested and proven efficient in secondary dressing of a wound of the wrist in which the radial and ulnar arteries had been divided. By its use, many lives might be saved on the battle-field, now lost from primary hemorrhage.

---

## Second Day, Thursday, September 26th—Afternoon Session.

Dr. John Shrady, of New York, read a paper on

### THE SHADOW LINE OF INSANITY,

in which he pointed out the faint dividing lines between the suspected and acknowledged forms. He said that the harmless classes of cases, attracting as they did but little attention in their several communities, might be developed under favoring circumstances into the more dangerous. They need not necessarily be tabooed or isolated, as they often contributed not a little to the general good, and might be even classed among the children of genius, being somewhat of the nature of excrescences, though of a startling variety. Of such were Coleridge, Lamb, De Quincy, Charlotte Bronté and Edgar A. Poe, all of whom were brilliant and exceedingly unpractical. As long as there were no particular explosive forces at work, they were safe enough, but although not subject to judicial isolation, on account of the law's jealousy for individual liberty, they might well bear watching. There were very few who might be designated as absolutely sane of mind, nor was there any great necessity that they should be thus constituted, since society was the mechanism and man the unit, and society was willing to pay for special graces at special rates. Here the individual is nothing, and society being strong, can well afford to defend itself.

### DISCUSSION ON THE TREATMENT OF HERNIA.

Dr. Joseph D. Bryant, of New York, opened the discussion. Six questions were propounded, and formally discussed by Dr. Bryant and others. They related to mechanical treatment, the injection method, the open or non-open method, medicinal and manipulative methods in strangulated herniæ, the technique of taxis, and treatment when gangrene existed.

Dr. Bryant said there could be no doubt but what the truss cured some cases, but the number was small. He thought, however, that its use should never be entirely dispensed with. The cure by this method was usually in the young. The patient should have three forms of truss, a strong one for use in heavy labor, a light one for use during rest, and a waterproof form for use in the bath. His conclusions on the question of mechanical treatment were: 1. No form of truss could be relied upon to cure any variety of simple irreducible hernia. 2. The manner of treatment of hernia, and that of its so-called cure by mechanical appliances, were such that cure by this means alone could not be relied upon. 3. Relief from annoyance of hernial protrusion might be had by means of hernial appliances to be worn during all unusual physical effort. 4. Apparent cures resulted from the resiliency or contraction of the tissues, and not from inflammatory process set up. 5. A hard, slightly convex pad with elastic steel spring attachment furnished the best hernial appliances. 6. Suspension, elevation, and contraction of irreducible hernial protrusions were the main indications for mechanical treatment. He had had no experience with Heaton's injection method. There were certainly other better operative methods.

Regarding operative methods, he drew the following conclusions:

1. The open method of treatment was the most rational and simplest method for the radical cure of hernia. 2. That the additional time for treatment required by the open method was time well employed, since there was less likely to be a return than from any other method. 3. That the interweaving of the sac with the pillars of the ring (a new method of his own), followed by the open or closed method,

afforded in many cases equal, if not greater, security than any other method.

Morphine injections and hot-water baths with elevation of the part, were the most available means aside from operative interference and taxis. Taxis should not be continued longer than fifteen minutes. That length of time was sufficient if it were properly employed; if not so employed, any length of time was too long. Repeated attempts at reduction by taxis on the part of different physicians was pernicious.

The following conclusions were drawn concerning gangrene: 1. When gangrene of the intestine had taken place and the condition of the patient would permit, intestinal repair should be practised at once and the gut returned to the cavity. 2. When gangrene occurred, presumably involving a portion of the upper two-thirds of the intestine, the intestine should be repaired at once and the gut returned, even if the immediate result should be somewhat doubtful. 3. When gangrene had occurred and the condition of the patient would not permit of immediate operation, a temporary artificial anus should be made. 4. It was better to form an artificial anus when the medical attendant was not acquainted with the details of the more difficult procedure.

Dr. Milligan discussed the mechanical treatment. In the Hospital for the Ruptured at Forty-second Street they had found the simple apparatus of Dr. Knight answer in most cases, but in some other methods had to be resorted to. The instrument demanded differed according to the variety of hernia (he considered only the inguinal), which might be divided into three: (1) Simple bubonecele, without viscus in the canal; (2) where the hernia had passed the external ring without obliteration of the canal; (3) where the canal was obliterated and the external ring enlarged. The first two varieties were controlled by almost any kind of truss. Five kinds of trusses were described.

Dr. Roswell Park discussed the open and non-open operative methods, giving the preference to the former. The cicatrix left by the closed method was much broader, being three-eighths to three-fourths of an inch in width, and must, he thought, undergo stretching and absorption. In his cases the patient wore no truss after the operation, since he believed its pressure encouraged absorption of the cicatricial tissue. He was opposed to injections. The risks of the operation were not greater than those of railroad travel. He was favorably impressed with Dr. Bryant's description of his method of interweaving the sac with the pillars. The last few years he had hardly ever employed drainage, the wound being aseptic. He had operated sixty times, and had heard of a return in only three cases, and suppuration in one or two.

Dr. W. T. Bull, of New York, read a paper on

OPERATIVE METHODS,

in which he cited what he regarded as formidable objections to the closed method, particularly the liability of recurrence. No operation could be regarded as absolutely radical. A return of the hernia had been observed at the Hospital for Ruptured and Crippled in persons who had submitted themselves to the different operative procedures. He reported 72 cases in which he had operated over a year ago. Of this number 38 were treated by ligature, excision, and suture; 34 by ligature and excision. There were three deaths, which, however, could not be attributed to the operation. In 29 cases the hernia was reducible, in 31 irreducible, in 12 strangulated. Of the 78 cases only about 40 were seen after leaving the hospital. The percentage of cases relapsing within twelve months after treatment by ligature and excision, was 62; after treatment by ligature, excision, and suture, 75. The result caused disappointment so far as radical cure was concerned, but when relapses occurred the hernia was less difficult to control by truss. He advised a light truss after the operation. The open treatment reduced to a minimum the danger of septicæmia.

Drs. D. M. Totman and Leroy J. Brooks discussed the medicinal and manipulative methods in

STRANGULATED HERNIÆ.

Dr. Detmold said that, about fifty-two years ago, a young lady, just married, came to him and asked if a hernia could be operated upon. She had a small femoral hernia which her husband took for a bubo derived from improper courses, and refused to have anything to do with her. Dr. Stevens and others discountenanced an operation, and he had at that time no precedent to go by. However, he made an incision down to the crural canal, avoiding the vessels, filled the canal with lint several weeks, and thus cured the hernia. The husband was so moved by the devotion manifested by his wife, that he returned to her and nursed her through the long illness.

Dr. Marcy said the fault with most methods of operating was failure to close the inguinal canal in the oblique line observed by nature. The sac should be removed, the cord pushed inward, a row of sutures placed in the bottom of the wound laying open the canal from the lower angle to the upper, and another row of sutures in the more superficial parts in the opposite direction. Thus, the obliquity of the canal and its normal length were preserved. Animal sutures should be used, buried. He did not confine the patient to bed, nor advise a truss. All who had trouble with the hernia should be operated upon. He believed over ninety per cent. of his cases remained cured, and he had operated about one hundred times.

Dr. E. M. Moore said that about 1837, when he was a medical student, Dr. Pancoast had him bring in four patients with hernia, on whom he made practically hypodermic injections into the sac of tincture of cantharides, with the view of setting up adhesive inflammation and obliteration of the sac. This was done at a time when they had great fears of injury to the peritoneum. The result was what had been desired, the hernia was apparently cured in each instance, although the cases could not be followed up.

When Heaton began his method of treatment, he placed a young man under Dr. Moore's care into whose hernia he injected with a glass syringe (after making an incision with the knife) several drops of oil of cloves. The man afterward followed his former occupation of porter in a hotel, wore no truss, and had no return.

In one case Dr. Moore inserted needles and turned the sac subcutaneously in such a way as to bring its surface together, then inserted a row of pins along the line of the canal and across at the commencement, which held the sac in the new position and caused adhesive inflammation and cure of the hernia.

The subject was further discussed by Drs. Didama, Armstrong, Van Danhoff, and Manley.

At the evening session Dr. E. K. Dunham exhibited lantern views of bacteria, and Dr. Stewart a urethrograph.

---

Third Day—Friday, September 27th—Morning Session.

The following papers were read by title: "The Use and Abuse of the Forceps in Obstetrics," by J. P. Garrish, M.D.; "Observations on Dislocations of the Hip," by U. C. Lynde, M.D.; "Two Cases of Angular Deformity of the Knee-joint," by L. H. Sayre, M.D.

Dr. E. K. Dunham, of New York, read the address on medicine (see p. 367) entitled

THE BACTERIOLOGICAL TEST OF DRINKING-WATER,

Dr. H. O. Marcy, of Boston, read a paper entitled

THE CURE OF HÆMORRHOIDS BY EXCISION, AND CLOSURE WITH THE BURIED ANIMAL SUTURE.

The paper covered in a degree nearly the entire field of hæmorrhoids, but dealt more particularly with the operative methods in treatment; pointing out the objections to Allingham's procedure, that by crushing, and by injection of carbolic acid, etc. The method practised by the au-

thor was a modification of Whitehead's, which, he said, was a distinct advance over procedures previously discussed. Among the conclusions were: 1. That the ligation of tissues for the purpose of producing necrosis, and resulting antiseptic decomposition, should to-day be considered unsurgical, and never to be resorted to in any part of the body. 2. The destruction of tissue by the actual cautery was provocative of pain and suffering, and was unwarranted in that it was unnecessary, with rare exceptions, in surgery. 3. The dissection and removal of the hæmorrhoidal plexus of diseased vessels, was as rational and scientific as the dissection and removal of diseased tissues elsewhere; that the danger of hemorrhage from excision of these structures had been greatly exaggerated. 4. That by the method which he (Dr. Marcy) practised, the operation could in no sense be considered a bloody one; it was simple and easy to do after a little experience; there was no material hemorrhage, the important blood-vessels being secured before division by continuous encircling sutures, which served still further the purpose of holding at rest the divided tissues. Necrosis of the parts was entirely avoided, and with the care practised in modern antiseptic surgery the wound was maintained aseptic. The superficial tissues were accurately coaptated, so that no stitch acted as a foreign body. He used animal sutures altogether, that from the tail of the kangaroo, the fascia latæ of the moose, or possibly that of the buffalo, although this could scarcely be obtained on account of extinction of the animal. The advantages of the buried suture over the excision method of Dr. Whitehead were: It secured constriction of the blood-vessels before division; more accurate readjustment and closure of the parts through continuous sutures which were buried and incorporated in the tissues. The time required in the use of interrupted sutures was longer.

Dr. Darwin Colvin read a paper entitled

### REPORT OF A CASE OF ATAXIC PARAPLEGIA.

He first saw the patient, a young farmer, in March last. The preceding January he noticed a weakness of the legs, which, after a time, developed into unsteadiness of gait. At no time had there been pain, but occasionally there was some aching in the sacral region. In March he was walking with a cane, could extend the leg with force, while flexion was weak. Increased difficulty in turning was very apparent. The patella reflex was much exaggerated, and there was well-marked ankle clonus; sensation was unimpaired except very slight numbness and tickling. At no time was there constriction around the waist, no inco-ordination of hands or arms, no loss of sexual power, sphincters normal, no muscular atrophy; inability to stand with the heels together and eyes closed; appetite good. The gait was not that of locomotor ataxia, from which affection the author gave the differential diagnosis.

Dr. Charles S. Bull, of New York, read a paper entitled

### EXTRACTION OF CATARACT WITHOUT IRIDECTOMY, WITH REPORT OF ONE HUNDRED CASES.

Useful vision was regained in all but one. In that one the blind had been rendered blind previous to operations by frequent attacks of iridochoroiditis. No eye was lost from suppuration. Fifty-two patients were males, forty-eight females; the youngest thirteen, the oldest eighty-seven years of age. Complications of different kinds existed in many of the cases. Reduction of the prolapsed iris after the extraction of the lens occurred spontaneously in 56 cases, and was replaced by the spatula in 44. In 83 there was neither incarceration nor secondary prolapse of the iris. In 53 there were no posterior synechia or adhesions of the iris to the lacerated capsule. In 47 these adhesions were present, and in 10 of these they were due to plastic iritis. The healing process was normal in 86, though in some the process was slow. Iritis of the mild plastic type occurred in 10 cases, and retraction of the iris toward the ciliary processes in 3; loss of corneal epithelium in 2, "striped" keratitis in 1. The wound became infiltrated in 3, necessitating the use of the galvano-cautery. Choroiditis and hyalitis occurred in 2 cases, and irido-choroiditis with occlusion of the pupil in 2 cases. Capsulitis occurred in one.

Accidents during the operation were, 1, loss of vitreous in 13; 2, hemorrhage into the anterior chamber in 2; 3, complete collapse of the cornea in 2; 4, dislocation of the lens in 3; 5, the lens was removed with the blunt hook in 5.

The duration of treatment varied from eleven to forty-seven days. Secondary or after-operations in 53 cases. Discission or laceration of the capsule in 50, and excision of a piece of capsule in 3. The resultant degree of vision was as follows: $\frac{20}{15}$ in 26 cases; $\frac{20}{20}$ in 13; $\frac{20}{25}$ in 24; $\frac{20}{30}$ in 22; $\frac{20}{40}$ in 21; $\frac{20}{100}$ in 10; $\frac{20}{200}$ in 2; counting fingers at several feet, in one.

### DISCUSSION ON THE NEW HYPNOTICS.

Dr. W. H. Flint, before reading his paper opening the discussion, permitted Charles Rice, Ph.D., to first make his remarks. Mr. Rice said the demand for the new hypnotics was in about the following order, beginning with that least consumed: Hypnon, amylene hydrate, urethral, sulphonal, paraldehyde. Paraldehyde was used more than sulphonal because cheaper. Hypnon was objectionable because of its disagreeable taste; amylene hydrate because of its bad after-effect. Sulphonal was the best hypnotic of the group, but was almost insoluble in water, and it was difficult to get a quick effect from it.

The white crystalline sulphate of hyoscyamin was cheaper than the alkaloid hyoscine, but the latter was much more efficient as a hypnotic and would, when it should become cheaper, take the place of the former.

Dr. Wm. H. Flint reviewed the literature of the new hypnotics, and then gave conclusions based principally on his own experience with them. He had used sulphonal most as being the most efficient or desirable of the new hypnotics. Its physiological action had not yet been thoroughly established. As a hypnotic it was valuable in some forms of insanity, neurasthenia, acute sthenic febrile diseases, opium habit, gastric irritability, and some cases of anæmia. In gastralgia, gastritis, and some other conditions, it was contra-indicated. Toxic symptoms were not likely to manifest themselves unless the dose exceeded thirty grains in the adult. A large dose caused fatigue, depression, vertigo, tinnitus aurium, and œdema of the eyelids; it might cause even collapse. It was best administered by the mouth, with hot beverages or liquid food an hour and a half before the desired action. He had not yet seen a sulphonal habit. There had been about eighty per cent. of successes in his cases. He had administered amylene hydrate in thirty-eight cases of insomnia, in various diseases, obtaining hypnotic effects in over seventy per cent. Its physiological effects were similar to those of alcohol. Its odor was disagreeable It should not be given in gastric disease, because slightly irritating. He had recently used paraldehyde in thirty-five adult cases for insomnia, with successful results in seventy-two per cent. It was not irritating to the stomach. If too large doses were given a long time, a condition resembling chronic alcoholism might develop. It was best given in soft capsules. He spoke less favorably of the other hypnotics.

Dr. John G. Truax continued the discussion with a paper. Sulphonal had proven, in his experience, more effectual, and applicable in a larger number of cases, than any of the other new hypnotics. It had been of most benefit in the restlessness, cough, and slight pains of phthisis pulmonalis. The conditions in which the new hypnotics were useful were those in which there was not much pain nor acute inflammation, absence of violent mania, where delirium did not depend upon congestion. They would not take the place of the older hypnotics in the class of cases in which these were applicable.

Dr. Squibb expressed some hesitation in discussing the

subject. His views were conservative. The new hypnotics were large in number, and would yet be larger. The same was true of the opium preparations ten years ago. This could be largely accounted for by the remark of one of the speakers, that there were "millions in it" to the successful advertiser.

It would be observed that none were susceptible of hypodermic use; they were slowly absorbed, owing to the nature of the fluids in the stomach. In the stomach of the healthy, who needed no hypnotic, sulphonal was absorbed more readily. Artificial alkaloids were being constantly made by the chemist from natural sources. The molecules of a given agent, as that from which hyoscin or quinine were obtained, had their cleavage in different directions, according to the reagent applied, and thus was produced the alkaloid or derivation leading up to it, but which had no existence prior to the labors in the laboratory.

### A CASE OF AMPUTATION OF THE HIP-JOINT WEARING AN ARTIFICIAL LEG.

DR. L. H. SAYRE presented a young man who, about seven years ago, suffered from an attack apparently of rheumatism of the right knee. He continued an invalid from knee-joint disease until about six months ago, when Dr. Reginald Sayre performed amputation at the junction of the lower with the middle third of the femur. It became evident afterward that disease existed in the hip-joint, and it was decided to amputate in a manner, if possible, to permit of future use of an artificial limb, instead of in the old way and condemning the patient to the use of crutches all his life. Consequently the circular incision through the soft parts was made below the trochanter, and the femur enucleated through a longitudinal incision reaching above the trochanter. When presented, the patient was wearing an artificial limb for the second time, the muscular stump supplying attachment and motion. He believed that to his brother belonged the credit of doing this operation for the first time.

DR. L. A. SAYRE said he had suggested a similar amputation with the same object in view, fifteen years ago, but had not had occasion to perform it. He was delighted at the result in this case.

DR. JOHN G. ORTON was elected president for the ensuing year.

## Correspondence.

### INTUBATION FOR THE REMOVAL OF FOREIGN BODIES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The interesting case reported by Dr. S. J. Meltzer in THE RECORD of September 21st, in which intubation was successfully practised for the removal of a foreign body from the air-passages, suggested the following remarks:

The size of the croup tubes was not modelled after the normal larynx, but they were so constructed as to avoid dangerous pressure when the lumen of this organ is almost obliterated by inflammatory infiltration of its mucous membrane and submucous tissues. To facilitate the extrusion of foreign bodies from the air-passages, therefore, a tube of much larger calibre can be used. It should be constructed as follows: not over an inch long, cylindrical in form, of very thin metal, perfectly straight, with small flanges laterally, none anteriorly, and having a bore at least three times as great as that of the tubes now used in the treatment of croup. The obturator should fit perfectly at the distal end, otherwise it would be difficult to insert.

No retaining swell is necessary, as the size alone is sufficient to hold it in place.

With a strong string attached, such a tube may be allowed to remain in the larynx twenty-four hours if required, without injury, but if retained for the same length of time in a case of croup would undoubtedly produce sloughing of mucous membrane of the subglottic division of the larynx. This is the smallest portion of the upper air-passage, and at the same time the most unyielding, because it is completely surrounded by cartilage. There is no danger of injury to the vocal cords, even if worn for a much longer time.

Foreign bodies enter the larynx during inspiration, when the vocal bands are widely separated, but their expulsion is prevented by the spasm excited by the slightest irritation applied to the under surface of these bands.

The introduction of such a tube as I have described overcomes this difficulty, and at the same time gives rise to a violent attack of coughing, which should prove successful in the great majority of these cases when the foreign body is not impacted in the lower air-passages.

Taking advantage of gravity by holding the patient's head downward, as was practised by the mother in Dr. Meltzer's case, is also worth trying, particularly if the foreign body be heavy.

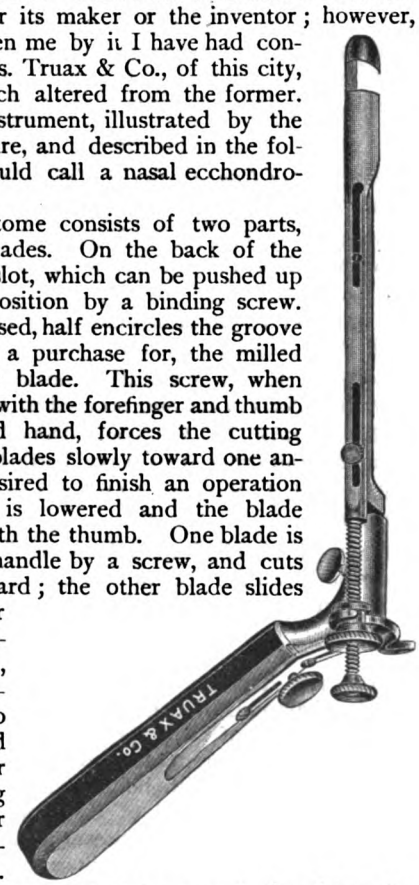
J. O'DWYER, M.D.
967 LEXINGTON AVENUE.

## New Instruments.

### A NASAL ECCHONDROTOME.

BY MOREAU R. BROWN, M.D.,
PROFESSOR OF RHINOLOGY AND LARYNGOLOGY AT THE CHICAGO POLICLINIC, CHICAGO, ILL.

SOME time since, a foreign-made instrument, said to have been intended for the purpose of operating on the nose, was put into my hands. I have not been able to ascertain the name of either its maker or the inventor; however, from the idea given me by it I have had constructed by Messrs. Truax & Co., of this city, an instrument much altered from the former. This improved instrument, illustrated by the accompanying figure, and described in the following lines, I would call a nasal ecchondrotome.



The ecchondrotome consists of two parts, the handle and blades. On the back of the former is a steel slot, which can be pushed up and fastened in position by a binding screw. The slot, when raised, half encircles the groove in, and thus forms a purchase for, the milled nut on the short blade. This screw, when turned, preferably with the forefinger and thumb of the disengaged hand, forces the cutting edges of the two blades slowly toward one another. If it is desired to finish an operation rapidly, the slot is lowered and the blade pushed forward with the thumb. One blade is made fast in the handle by a screw, and cuts from within outward; the other blade slides along the former and cuts in the opposite direction, *i.e.*, from without inward. The two screws which hold the blades together prevent the cutting edges of the latter being pressed together and blunted. The blades can be turned so as to operate in either the left or right nasal cavity.

This instrument will take the place of the saw, the knife, and the chisel in many intranasal operations, particularly in removing ecchondroses and cancellous exostoses, which comprise, as is well known, the majority of all growths from the septum of the nose.

In suitable cases one can operate more rapidly and easily with the ecchondrotome than with any other instrument.

In using the knife to remove cartilaginous growths from the septum the operation must often be finished with the saw or chisel: not so with the ecchondrotome, as it will readily cut its way through these formations.

The principle on which this instrument works is similar in some respects to the Mackenzie tonsillotome.

126 STATE STREET, CHICAGO, ILL.

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 22 to September 28, 1889.*

POPE, BENJAMIN F., Major and Surgeon. By direction of the Secretary of War, the leave of absence granted in S. O. No. 54, August 17, 1889, Department of Texas, is extended one month. Par. 6, S. O. 224, A. G. O., September 26, 1889.

LORING, LEONARD Y., Major and Surgeon. By direction of the Secretary of War, his station is changed from Fort Mojave, Ariz. Terr., to Fort Wingate, N. M., and he will report for duty at the latter place accordingly. Par. 7, S. O. 219, A. G. O., September 20, 1889.

CHAPIN, ALONZO R., Captain and Assistant Surgeon. Granted leave of absence for fourteen days, with the approval of the Secretary of War. Par. 10, S. O. 223, A. G. O., September 25, 1889.

BURTON, HENRY G., Captain and Assistant Surgeon. By direction of the Secretary of War, will report in person on expiration of his present sick leave of absence, to the commanding officer at David's Island, N. Y., for temporary duty at that station, and by letter to the superintendent recruiting service. Par. 3, S. O. 223, A. G. O., Washington, September 25, 1889.

*Official List of Changes in the Medical Corps of the United States Navy for the week ending September 28, 1889.*

GORGAS, A. C., Medical Director. Detached from Examining Board and ordered to hospital, Philadelphia, Pa.

HORD, W. T., Medical Director. Detached from hospital, Philadelphia, Pa., and to wait orders.

BOGERT, E. S., Medical Inspector. Detached from New York Navy Yard and ordered to Examining Board.

MCMURTRIE, D., Surgeon. Detached from U. S. S. Vermont, and ordered to Navy Yard, New York.

BABIN, H. J., Surgeon. Ordered to the Receiving Ship Vermont.

HALL, C. H. H., Passed Assistant Surgeon. Resigned from the Naval Service, to take effect November 1, 1890, and resignation so accepted.

FOR THE RELIEF OF CORYZA.—Dr. Köhler recommends inhalations of camphor as affording great relief in the early stages of an acute coryza. He puts one teaspoonful of powdered camphor in a rather deep vessel, half fills the latter with boiling water, and covers it with a paper cone. The end of this cone is torn off so as just to admit the nose. The warm camphor-laden vapor is then inhaled through the nose, not the mouth, for a period of from ten to fifteen minutes. This procedure is repeated every four or five hours. After the third inhalation, even the most stubborn catarrh, says Dr. Köhler, will be found to have completely disappeared. Any laryngeal catarrh, which may be present at the same time, will be found to be considerably benefited by the action of the camphor vapor.—*Zeitschrift für Therapie.*

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 28, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 58 | 7 |
| Scarlet fever | 26 | 3 |
| Cerebro-spinal meningitis | 0 | 0 |
| Measles | 10 | 1 |
| Diphtheria | 57 | 17 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

FRAULINA SCORBILIS IN DYSENTERY.—Dr. Aphel has obtained good results in the treatment of dysentery by means of fraulina scorbilis. He employs the powder in doses of seven grains every two or three hours. It possesses a stimulant and local astringent action, and is indicated chiefly in adynamic forms of the disease.—*Los Avisos Sanitarios.*

ANTIPYRIN IN DIABETES.—Drs. Gley and Germain Sée report a number of cases of artificial glycosuria in dogs, in which the good effects of antipyrin in this affection were well illustrated. To a dog passing thirteen grammes of sugar a day, one gramme of antipyrin per diem was given for eight days, at the end of which time the amount of sugar had fallen to eleven grammes. At another time the quantity of sugar was reduced by the same means from about ten to less than six grammes. Dr. Sée has also employed the drug in the treatment of glycosuria in the human subject with good results. Lépine and Porteret have shown that antipyrin has the effect of retarding the transformation of glycogen in the liver and muscles into glucose. M. Huchard has previously related several cases of polyuria and glycosuria, in which the exhibition of antipyrin was followed by good results. The latter author believes that this drug has a special utility in bulbar neuroses, among which he classes diabetes, polyuria, and exophthalmic goitre.—*Revue Générale de Clinique et de Thérapeutique.*

LEMON-JUICE IN NOSEBLEED.—In a case of rebellious epistaxis, which had resisted various modes of treatment, including plugging of the anterior nares, Dr. Fauchon obtained a cure by means of the local application of lemon-juice. An injection of the juice was made by a glass syringe into the nostril from which the blood was escaping, with the result of immediately arresting the hemorrhage.—*Revue Générale de Clinique et de Thérapeutique.*

TREATMENT OF THE POTATO DISEASE.—At a recent meeting of the Academy of Sciences of Paris, M. Prilleux sent a communication upon the treatment of potato disease by means of a copper solution which had been found useful for a similar affection of tomato plants. He experimented with some potato plants which were found to be in the initial stages of the disease although there were quite a number of black spots on the leaves. He selected nine hills for the experiment, reserving six others, without treatment, to serve for comparison. The liquid was carefully applied with a watering-pot so as to thoroughly wet all the leaves. The potatoes were dug up eleven days later, when from the nine hills treated one hundred and fifteen healthy potatoes were taken, none of which were diseased. From the six hills reserved for comparison fifty-three tubers were taken, and of these seventeen were diseased. The solution, called "bouillie bordelaise," was composed of six parts each of sulphate of copper and of chalk in one hundred parts of water.—*Journal d'Hygiène.*

### THE RELATION OF DIET TO URIC-ACID FORMATION.[1]

By WILLIAM H. DRAPER, M.D.,

NEW YORK.

IT is not my purpose in this brief paper to discuss the question of the origin of uric acid. Whether this substance is the penultimate of urea, or the result of the imperfect metabolism of glycocin in the liver, are questions which are still involved in much obscurity. Nor do I intend to consider the relations of the real or apparent increase of uric acid and its salts in many pathological conditions that come under the observation of the practical physician, such, for example, as the febrile state, cirrhosis and cancer of the liver, splenic leukæmia, and many other diseases. I desire simply to call attention, very briefly, to the relation which deposits of uric acid and its salts bear to the ingestion of particular classes of foods, and their association with the special forms of indigestion which are observed in lithæmia and gout.

It is important to premise, however, that, in all probability, deposits of uric acid are properly to be considered as the indication and measure of the acidity of the urine, and consequently of the diminished alkalescence of the blood, and not perhaps so much the cause of the symptoms with which they are associated as themselves one of the effects of the imperfect blood-elaboration which is essentially the antecedent of the lithæmic state.

The blood, it must be remembered, in spite of the amount of acid material which enters it, always presents an alkaline reaction, and the maintenance of healthy nutrition doubtless depends upon the preservation, within certain limits, of what may be termed normal alkalescence. This equilibrium is secured partly by the organic and inorganic salts of the alkaline bases which are ingested with the food, and partly through the discharge of acids by the lungs, the stomach, the skin, and the kidneys. Whatever, therefore, tends to disturb this equilibrium must do so either through some defect in the conversion of the food-supply, or in the mechanism by which an excess of acid is removed from the body.

Assuming that uric acid is only one of the products of imperfect metabolism, and that it is associated with a diminished alkalescence of the blood, its relation to diet would seem to depend largely on the manner in which certain articles of food affect the reaction of the blood. Though the salts which are contained in our food are for the most part alkaline, a considerable amount of acid salts, such as the bicarbonates and acid phosphate of sodium, enters the circulation in the ingesta; another source of free acid is that which is present in wines and beers, and still another, and perhaps the most important, is found in the process of fermentation which goes on in the alimentary canal in the saccharine, amylaceous, and fatty elements of the food. It is especially in connection with the acid dyspepsia to which this fermentative process gives rise that we find deposits of uric acid and its salts. It is this form of indigestion, moreover, which is associated with the so-called lithæmic symptoms, and which is often antecedent to the development of gout.

[1] A paper read before the Practitioners' Society, May 24, 1889.

The generally received opinion is that an excess of albuminous food is the source of any excess in uric-acid excretion, and the practical deduction from this view is that nitrogenous foods should be more or less strictly prohibited in the diet of lithæmic subjects. While there can be no doubt that a nitrogenous diet increases, *pro tanto*, the amount of urea excretion, it is not so clear that it increases in equal proportion the uric-acid excretion; and inasmuch as a very large apparent increase of uric-acid excretion often occurs with a non-nitrogenous diet, it seems probable that deposits of uric acid and its salts in the urine are not so much the result of an excess of nitrogenous foods as of some condition of the blood which affects the solubility of this substance. The clinical evidence, based upon the effects of certain kinds of foods in producing showers of uric acid and sediments of urates in the urine, would seem to indicate that these phenomena are the result of an imperfect conversion of the carbohydrates, which gives rise to the introduction into the circulation of acids which diminish the alkalinity of the blood, and so impair its solvent power over uric acid.

It is the evidence of this nature, derived from a considerable clinical experience, to which I wish to ask your consideration. Many years ago my attention was called to the fact that gouty and lithæmic subjects exhibited a striking inability to digest the carbohydrates. I observed this in the victims of acquired as well as of hereditary gout, but especially in the latter, and often at a very early age. This inability to convert the carbohydrates I found manifested itself primarily in an acid dyspepsia, with increased acidity of the urine, with showers of uric-acid crystals or deposits of urates; and, secondarily, in the nervous derangements and the catarrhal lesions of the skin and mucous membranes which characterize the lithæmic state. Closer observation led me to the conclusion that the essential, and often the only successful, means of combating these derangements was the withdrawal, more or less complete, of the sugars and starches from the diet.

I am aware that the necessity for restricting the use of the carbohydrates in the dietary of gouty and lithæmic persons is now pretty generally recognized; but I think that the opinion still largely prevails that animal foods are not only responsible for the origin of gout and lithæmia but that the rational treatment of these disorders necessarily involves the more or less strict prohibition of these foods. So general, indeed, is the prejudice against the use of nitrogenous articles of diet in the treatment of gout—a prejudice founded mainly upon the teachings of the English authorities upon this disease—that it is only within a comparatively recent period that there has been any question about its correctness. Some of the later authorities, however, both German and English, recognize the baneful effects of the carbohydrates in the diet of gouty subjects, and strongly urge a diet composed largely of animal foods. My own experience leads me to believe that in aggravated cases of the morbid conditions under consideration a diet as rigidly exclusive of the carbohydrates as that required in glycosuria is necessary to control uric-acid formation and its consequences. The failure to recognize this fact often interferes very seriously, in my judgment, with success in the management of severe cases of this nature, for there is no therapeutic measure which, so far as I know, can compare with a properly regulated diet in controlling and preventing the miseries which are incident to this special derangement of nutrition.

Even those who are inclined to acknowledge the gen-

eral truth of this statement fail sometimes to appreciate the necessity of attention to details in carrying out the principle involved in what may be called the anti-lithæmic diet. It is only by careful observation and experiment in any given case that the dietetic cause of lithæmia can be ascertained. In the group of carbohydrates and their derivatives which enter into an ordinary dietary, it is often only necessary to exclude the fermented preparations of alcohol to correct the tendency to uric-acid formation. Wines and beers are perhaps more often responsible for this condition than any article of table use. After these I am inclined to class fruits as a frequent cause of lithæmia. It is not an uncommon experience to see attacks of gout even provoked by strawberries, watermelons, apples, and oranges, as readily as by Madeira and Burgundy. The reason why fruits are so prone to produce in gouty subjects primary and secondary derangements of digestion, is probably because of their saccharine property. They are to be classed among the sweets, and, as I have remarked, are often more apt to excite and perpetuate the lithæmic condition than other forms of sweet desserts. The cases are not very rare, in my experience, in which the exclusion of the carbohydrates may need to be extended to the farinaceous foods. I have known instances in which an almost absolute exclusion of them was required in order to control an acid dyspepsia, with its concomitant phenomena of uric-acid showers and deposits of urates.

I would not be understood as affirming that anything like the rigid exclusion of carbohydrates from the diet of lithæmic persons, which I believe to be sometimes necessary, is often required. Experiment only can determine what particular group of this class of foods is the source of mischief in the digestive process. It may be the fermented liquors, it may be fruits, it may be the sweet desserts, it may be the farinaceous foods, and it sometimes happens that the lithæmic subject will have to be as strictly debarred from indulgence in all of these things as the glycosuric.

There is one point in regard to lithæmia and its relation to diet to which it is important to refer, and that is, that the inability to convert the carbohydrates which we believe to be the real source of this condition, is occasionally intermittent, and is apparently excited or aggravated by nervous exhaustion from any cause, such as overwork, anxiety, or insomnia. This is especially common in neurotic persons. It is needless to observe that it is more common in persons of sedentary habits and intellectual pursuits, and its frequency is probably largely due to the failure to adapt the diet to the kind of work which the individual is called upon to perform. There seems to be good reason to believe that a diet composed largely of farinaceous foods is best adapted for the evolution of muscular work, since such a diet requires for its complete combustion a larger supply of oxygen; while for mental labor, and for the occupations which require only a limited amount of mechanical exertion and necessitate an indoor life, a diet composed largely of nitrogenous elements is most readily and perfectly assimilated. This idea, as far as a non-nitrogenous diet is concerned, is in accordance with what has been found by practical experience to be the most successful method of regulating the diet of animals and men from whom a long and steady evolution of muscular work is required. In regard to the superior adaptation of the nitrogenous foods for the development of the higher forms of vital energy the evidence is perhaps not so clear, though the experience of practical physicians in dealing with the common dyspeptic ailments of intellectual workers would tend, I think, to justify such a conclusion.

I have thus indicated in a brief and very imperfect manner what my own observation at least leads me to believe is the relation of uric-acid formation to diet. So far as the chemistry of this relation is concerned, I am aware that the explanation I have suggested is more or less speculative, and is, perhaps, entirely false. The points upon which, in conclusion, I would lay stress are: 1st, That deposits of uric acid and its compounds in the urine do not necessarily indicate so much any considerable increase in the formation of this substance as they do a condition of the blood which affects its solubility and the facility of its excretion. 2d. That this condition of the blood is one of diminished alkalescence. 3d, That this diminished alkalescence is produced by the entrance of acid substances into the circulation, largely through the fermentation in the alimentary canal, or the imperfect conversion by the liver of the saccharine and farinaceous elements of the food. 4th, and finally, That clinical experience, which, after all, in the present state of our knowledge of the chemistry of digestion, is our best guide, tends to show that the withdrawal, more or less complete, of the non nitrogenous foods, and the allowance of a larger admixture of the nitrogenous elements, constitute the most efficient means of controlling the formation and excretion of uric acid and the protean functional and tissue derangements which belong to the lithæmic state.

---

## A MALIGNANT TUMOR IN AN UMBILICAL HERNIAL SAC, WITH REMARKS ON THE ETIOLOGY OF CANCER.[1]

By DANIEL LEWIS, M.D.,

SURGEON TO THE NEW YORK SKIN AND CANCER HOSPITAL.

Mrs. B——, a widow, aged sixty-seven years, had suffered from umbilical hernia fifteen years, but had never worn a truss, having always reduced the protruding intestine easily and frequently, until about a year before applying to me for treatment.

She then began to suffer pain about the umbilicus, and so much soreness, that for the three preceding months she had not attempted to replace the tumor. The pain increased rapidly, and radiated to the stomach and pelvic regions, and a marked failure in flesh and strength, frequent vomiting, constipation alternating with diarrhœa, sleeplessness, and fever, compelled her to seek advice.

A monthly metrorrhagia of more or less severity had excited no especial surprise in the patient's mind, although continued more than twenty-five years beyond the usual period.

Upon examining the supposed hernia, I found a hard, nodulated tumor of a bluish-red color, the surface of which was slightly ulcerated, in the fold of skin at the upper portion. It extended nearly an inch beyond the border of the hernial ring, seemed quite movable with the skin, and it was a hope shared by Dr. S. N. Brockway, who saw the case with me, that the disease had not invaded the peritoneal cavity. An operation was advised, and after the patient was etherized, so that a thorough examination of the base of the tumor could be made, it was found to invade the ring, and all hope of a slight operation was abandoned. An elliptical incision being made, the tumor was dissected out as far as the ring, and then carefully examined for any intestinal contents. It evidently contained no gut, and was removed in order to facilitate examination of the parts beneath. The sac contained some omentum which was not diseased. The subperitoneal tissue was infiltrated as far as the finger could reach. It was thoroughly removed, and the wound then closed as after ovariotomy.

The patient rallied well after the operation, but died sixty hours afterward, apparently from shock, no peritonitis having developed.

It should be stated that an examination, while the patient was under ether, revealed a much enlarged cervix, but no sign of cancer, although the body of the uterus was so large as to suggest the possibility of its being the seat of malignant disease.

The first section from the apex of the tumor proved to be a large, round-celled, alveolar sarcoma.

---

[1] Read before the Medical Society of the County of New York.

The second section was from a portion of the base of the tumor just outside the neck of the sac, and is of especial interest on account of the gland-tissue which it contains, the origin of which is believed to be embryonic.

Dr. George T. Elliot has very kindly furnished me the following description of this rare form of tumor:

"The portions of the tumor removed from the umbilical region, which were received by me for microscopical examination, were hardened in alcohol, and the sections were stained with borax-carmin and pyrogallic acid and iron.

"It was not difficult to determine the nature of the growth, since portions of the sections were found composed of small spindle-shaped cells, with here and there a few large round cells, while in others these latter were arranged in more or less large alveoli formed by the bundles of connective tissue. In many of these alveoli, capillary blood-vessels, which were abundant throughout the tissue, penetrated in between the cells contained in them. From these features it was evident that the new-growth was a sarcoma composed of mixed cells, spindle-shaped and round.

"In addition to the sarcomatous tissue, however, there were found other histological elements which greatly increased the interest taken in the specimen. Distributed throughout the sections, more or less abundantly, glandular tissue was found, which was in every way identical with the glands of Lieberkuhn existing in the small intestines.

"The glands were composed of a basement membrane and columnar epithelium, and they were separated from one another by more or less connective or sarcomatous tissue. Some were unchanged, others were hyperplastic, while still others had undergone cystic degeneration.

"The tissue between them was more or less infiltrated with small round infiltration-cells.

"The presence of the intestinal glandular tissue in this tumor is not an extraordinary fact, but yet one which is rarely met with. Growths of this class occur at the umbilicus, and are known under the name of enteroteratoma. To understand the occurrence of these growths, it must be remembered that in fœtal life the ductus omphalo-mesentericus is prolonged into the umbilical cord, but normally disappears before birth. Abnormally, however, it may persist and develop into a tube resembling intestine, and either form a congenital diverticulum of the small intestines, or more rarely, if this development has occurred in the portion of the duct situated just in front of the navel, there remains a small tumor after the falling off of the severed umbilical cord.

"This seems to be the only way in which the presence of the intestinal glands in the tumor could be explained, that is, that the original growth was an enteroteratoma to which no attention had been paid, but which persisted and finally underwent sarcomatous degeneration. It seems, however, remarkable that it should have persisted so long before undergoing change."

The details of this case have been quite fully given for two reasons. In the first place, it is the only recorded case, as far as I have been able to learn, where malignant disease has been developed in an old hernial sac; and, secondly, its appearance therein is new evidence in favor of the fact, now fast becoming accepted by surgeons, that diseases which are perfectly non-malignant in the beginning may, and often do, prove to be the exciting cause of cancer.

Before proceeding further, permit me to state what we mean by the term "cancer." Much confusion still exists on that point, owing to the various diseases to which the term has been applied by different authors. Dr. Snow enumerates the following characteristics belonging to cancer:

1. Resistance to all known medicinal agents.
2. Proneness to invade other organs and tissues of the body than those in which it has originated.
3. Liability to recur after removal by caustics or the surgeon's knife.
4. The pain to which it commonly gives rise.
5. The tendency to destroy life.

Upon this basis the name of "cancer" becomes simply a general term to be used for convenience, to indicate any neoplasm which presents the characters enumerated, whether it be carcinoma in any form, any variety of sarcoma, epithelioma, or lymphadenoma.

This use of the term seems to me not only reasonable, but almost a necessity, for the accurate nomenclature of these malignant diseases can only be made by the microscopist, and is seldom necessary in determining the course of treatment which should be adopted.

The discussions concerning the etiology of cancer may all be classified under three heads, viz.: 1, Hypothesis; 2, analogy; 3, fact.

Under the first head we find the old theory of a dyscrasia—a peculiar condition of the blood manifested in the form of cancer. In the same category come those whose supposition is that heredity is the cause of cancer in a majority of cases, and Sir James Paget believes in all cases, if we could know the correct history.

In other words, because your paternal grandmother died of a cancer of the uterus at the age of fifty, and your brother's son, aged twenty-five, has a sarcoma of the neck or an epithelioma of the neck. we should attribute it to heredity as a cause. There would be just as much reason in attributing every other disease to heredity, for have we not all suffered more or less from disease with which our near and remote kinsmen were afflicted? The fact is that the distribution of a disease as prevalent as cancer would of necessity affect a relative of yours or mine now and then.

Among nearly two hundred cases of tumors, mostly malignant, in my own practice, not ten per cent. give any family history of cancer.

The attempt to definitely and forever settle the etiology of cancer, by comparing it with tubercular disease as its analogue, is now in the height of public and professional favor.

Nearly all writers on cancer, for the past hundred years, have discussed the same question, and arrived at varying conclusions, all agreeing on one point only, that both diseases usually terminate fatally.

Since Koch's discovery of the bacillus of tubercle, we have been told that the bacillus of cancer would soon be discovered. A committee appointed by the British Medical Association, after a very careful investigation, has reported a negative result.

Scheurlen's discovery of the bacillus of cancer has not been confirmed by others, or successfully maintained by himself. There, however, remains the possibility, and even hope, that the microscope will yet reveal the actual cause of cancerous growths; but even then we shall be obliged to depend upon facts gleaned from clinical experience for effective methods of treatment. Hence the history of such a case as we have described becomes important, as it presents an unusual, if not unique, instance of the long continued irritation of an unretained hernia, finally causing a neoplasm of a very malignant type.

Nothing can be plainer to a careful observer than that a prolonged local irritation, such as a broken tooth upon the lip or tongue, inflamed hemorrhoids in the rectum, or chronic inflammation in a lacerated cervix uteri, will very often cause cancer. This case adds another possible cause, and there can be little doubt that if, in the precancerous stage, as Mr. Hutchinson has named it, a proper truss had been applied, she would have been alive to-day.

The statement has been made, concerning traumatism in these cases, that a prolonged irritation will cause carcinoma, while a sudden injury, like a single blow upon the breast, will be followed by a sarcoma, in case any tumor occurs. From a study of my own cases, there seems to be no foundation for the opinion. It is a matter of no clinical importance, however, as one variety is liable to be as malignant as the other.

Statistics are not yet ample enough to be of great value on this subject, but enough is known to justify the statement that traumatic causes play an important part in the etiology of cancer.

Tumors of non-malignant type often prove a source of irritation to adjacent tissues, and so cause cancer, or the tumor itself degenerates into a disease of a malignant character. Of this class the following is a good illustration: A man, aged fifty-five, with a wen on the vertex, one inch and a half in its longest diameter, which had existed for a score of years or more, accidentally struck it against a sharp piece of wood, which, if I remember rightly, caused slight bleeding. Inflammation of the tumor followed, then ulceration and sloughing, which was followed, after a few weeks, by cancerous disease of the entire border and even base of the ulcer. There was no family history of cancer.

The instances in which cancer has developed in congenital moles, warts, in syphilitic ulcers of the tongue and lips, in the penis where an old phimosis has irritated the organ, and in cicatrices of various kinds, more especially after burns, have been often noted.

Dr. A. D. Pomeroy referred a patient to me a few days ago, who was injured several years ago by a splinter of hot iron striking the bridge of the nose, and glancing to the right, ploughed its way nearly to the internal canthus. It healed pretty promptly, but had always been a little tender near the eye. For a few months past it has been more troublesome, and when he presented himself at the clinic a well-marked epithelioma had developed in that portion of the cicatrix nearest the angle of the eye. In the meantime, since the injury the man had reached the age of forty-nine, when cancer is much more liable to occur than in earlier years.

At least four cases are now on record where epithelioma has developed on a psoriatic base—two by Dr. White in 1885, one by Cartay in 1878, and one by Hebra.

In White's and Hebra's cases there was a transition of warty growth of the plaques, a form to which the name psoriasis verrucosa is given. These cases, while showing that psoriasis is not simply a parakeratosis, but also of inflammatory nature, renders a prognosis of much greater moment in cases where any appearance of a warty growth is manifested

All these instances simply teach us that any prolonged irritation in organs most subject to cancer is liable to set up the disease, and, from the practitioner's stand-point, the successful treatment of such cases depends to a great extent upon prompt and thorough eradication of all these predisposing causes of the disease when possible.

Before closing, permit me to enter a strong protest against the common practice of trying the effect of mild caustics, such as nitrate of silver, pyrogallic acid, resorcin, and many others, upon these malignant diseases. Nearly always such applications stimulate the progress of the disease, and very seldom do any good whatever. This is eminently true of the galvanic current as applied to the surface of tumors.

A scirrhous tumor of the breast, which the physician in charge permitted me to examine recently, had made such remarkably rapid progress that some special cause was sought for, and found, as I believe, in the mild and frequently repeated galvanization of the tumor by an overzealous advocate of that remedy.

62 Park Avenue.

Is Saccharin Injurious?—M. Dujardin-Beaumetz having been quoted as saying that saccharin was injurious, writes to the *Journal de Médecine de Paris* that he was misrepresented. He regards saccharin as a most valuable acquisition in the dietetic treatment of diabetes. But what he had protested against was its use in the adulteration of food. Such use, he maintained, was not only fraudulent but was injurious, not because the substance is in any sense poisonous, but because it is innutritious, and the consumer gets what he supposes is a food but which is not.

## A CASE OF RHINOLITH AND TWO CASES OF A TOOTH IN THE NOSE.

By JONATHAN WRIGHT, M.D.,

Brooklyn, N. Y.

While rhinoliths are by no means very frequently found, yet they are not so rare as to be unknown in the experience of any laryngologist who sees annually a large number of cases of nasal disease. They are more often seen in dispensary practice than among private patients. This, no doubt, is due to the neglect of symptoms caused by the presence of a foreign body in the nose among this class, and to the fact that the children of well-to-do parents are more carefully watched, and the introduction of foreign bodies prevented or detected. A rhinolith always has as a nucleus a foreign body which, in the great majority of cases, whatever the age of the patient, has been introduced into the nose during childhood, although it is the exception to obtain a history of the event. After the lapse of time it gradually becomes coated with lime-salts, deposited upon it by the nasal secretions, rendered abnormally abundant by the irritation of its presence. The longer it remains the larger it grows, and the greater the local irritation it causes. The nucleus is most frequently a relatively small object, because a large one soon causes such symptoms as to be noticed by the parents of the child. or by the patient himself, and thus becomes the subject of investigation. The nucleus may be anything, and nearly everything has been found, from shoe-buttons and pieces of coal, to maggots and parasites. The rhinolith, as it grows by the accretion of lime-salts, hollows out for itself a cavity in the nasal fossa, usually the inferior meatus, and this cavity may be of considerable size. The bony walls may be encroached upon, causing necrosis of bone, but the destructive process is rarely, if ever, extensive. After a time, a condition of the nose exists which, at first glance, has every appearance of idiopathic ozæna. There may even be atrophy of the mucous membrane. This appearance is always unilateral, while ordinary ozæna rarely, though occasionally, is. A frequent symptom is excessive epistaxis, especially when the nasal fossa is probed. The foul smell, which may be that of necrosed bone, often resembles syphilitic ozæna. Pain of varying intensity may be present, as well as various reflexes, such as sneezing, coughing, asthma, neuralgias—in short, any or all the symptoms due to intra-nasal pressure, or to irritation from other causes.

The nasal discharge is usually copious, and may be thick, forming crusts easily, or muco-purulent, stained with blood, or simply watery. Occasionally portions of the lime salts may come away with the discharges, the patient speaking of them as "gritty." Such symptoms, when unilateral, are almost pathognomonic of a foreign body in the nose, which may or may not have lime-salts around it.

A rhinoscopic examination reveals, as a rule, no foreign body to the view, because it is imbedded in its cavity and surrounded by hypertrophic mucous membrane; cleansing the nasal fossæ by a spray fails to bring it to sight. The application of cocaine, by shrinking the tissues and enlarging the field of vision, may often disclose the source of the trouble. The probe is the most reliable means of diagnosis, the grating of the hard body revealing its presence. The presence of dead bone from syphilitic necrosis is practically the only other condition which can deceive the experienced examiner. This can still further be eliminated by measuring with the bent probe the limits and the shape of the bared surface, and by its mobility.

If the foreign body is not easily extracted at the first sitting, it is well to give the patient an alkaline nose-wash with a syringe, and direct him to keep the nose clean for a few days by the use of them. Often, at the next visit the discharges and the swelling, as well as the subjective symptoms, will have largely abated. A stiff probe is often useful in prying the body out of its cavity. By bending a right-angled hook on the end of the probe the body may

be dragged out by this simple means. A snare may be used to encircle it, washing the nose out from behind with a post-nasal syringe; a sudden expiratory effort by the patient, after the object has been dislodged, may bring it out. The best forceps for the purpose are those devised for general nasal work by Dr. C. H. Knight, of New York City. I believe there have been various instruments specially devised for extracting a foreign body from the nose. I doubt if they are necessary.

Of late years, the journals devoted to laryngology and rhinology have abounded in descriptions of cases of rhinoliths and other foreign bodies in the nose, and a reference to them will easily disclose the literature of the subject. The case of rhinolith reported here is one of several that have come under my observation, distinguished from others simply by its size and the character of the nucleus.

D. L——, aged thirteen, a schoolboy, applied at the Demilt Dispensary for treatment on April 27, 1888. Three years previously his nose had begun to trouble him, bleeding easily and discharging offensive material, and always from the left side. No history could be obtained of the introduction of any foreign body whatever.

There was marked tenderness to touch on the left side of the nose. An intra-nasal examination showed an object covered with secretions lying in the left inferior meatus. A foul odor was emitted from this side of the nose. The object seemed about the size of a hazel-nut, and gave a grating sound and sensation on the impingement of a probe. It was necessary to break it into several fragments before extraction. It was found to consist of two layers of hard calcareous material, between which sponge-tissue could be plainly distinguished. The calcareous material had infiltrated only the outer portion of the sponge, leaving the central part free from it. The rhinolith had hollowed out for itself a nest between the septum, the inferior turbinated bone, and the floor of the inferior meatus; all nasal symptoms soon subsided after the extraction.

As has been said, many such cases have been reported. The presence of a tooth in the nose is, however, a very rare circumstance. There is a record of one case,[1] where a right upper canine tooth was removed from the left orbit of a child. This was evidently a dentigerous cyst, which must have begun development at a very early stage of embryonic life. Many cases of dentigerous cysts have been reported, and they are not by any means confined to the maxillary regions.

Dr. Wyeth,[2] several years ago, reported to the New York Pathological Society a case in which a displaced tooth was found in the antrum of Highmore. Dr. Griffin [3] found a tooth growing upward in the nose in a case of cleft palate. This produced no symptoms. Dr. Marshall,[4] and Dr. Ingalls,[5] of Chicago, have each reported a case in which the tooth had apparently ulcerated through into the nose, from the upper jaw. It is doubtful how the teeth in the cases reported by Schaeffer,[6] Roy,[7] and Hall [8] became nasal inhabitants. These six cases are all that I have been able to find recorded, after a careful search, though other reports may have been overlooked. In all the cases reported the teeth were the anterior ones, canines or incisors; and the reasons are obvious, since the posterior ones, if inverted, as in Griffin's case, would grow into the antrum, and probably produce no symptoms. I have seen skulls in which a tooth had attained full growth within the alveolar process of the superior maxilla without emerging from the bone at any point. Where ulceration takes place, the progress of a bicuspid or tricuspid upward would be very unlikely to occur, from the shape of its root. If it should occur, as in the case of Wyeth, it would, from its situation, be most likely to be discharged into the antrum.

The first of the cases related here is instructive as illustrating the migration of an object through bony structure, while the second case was evidently originally one of the extra-alveolar development.

CASE I.—Mary V——, aged thirty-five; married; came to the Demilt Dispensary February 21, 1888. Her previous and family histories had no bearing on the case. Four years previously she had all her remaining teeth, nine in number, extracted from the upper jaw. The last one, a lateral incisor or canine, on the left side, she had extracted during nitrous oxide narcosis. The dentist told her he thought he had left a piece behind, but could not detect it on probing. There was a good deal of gingival tenderness afterward, which soon subsided. These facts were elicited from direct questioning after the nature of the trouble became evident, the patient having had no suspicion of the connection between the tooth episode and the nasal symptoms which followed six months later. At that time the left side of her nose began to trouble her, by being "stopped up" at times, and there was a slight discharge. For two years previous to her application for treatment there had occasionally been a good deal of bleeding, and the obstruction, together with the nasal discharge, had steadily increased. For the last six months the nose on the left side had been painful and sensitive. An intra-nasal examination showed marked hypertrophy of the nasal mucous membrane on the left side. It was red and inflamed, and bled easily. A probe detected a rough, hard surface about an inch and a half from the left anterior meatus, on the floor of the nose and close to the septum. Small pieces of calcareous matter or bone could be crumbled off with the probe. The patient was given an alkaline wash with a syringe. Two weeks later she again presented herself, bringing with her a small, flat sequestrum which she had washed out of her nose. After the thorough application of cocaine, by means of a probe and the forceps the single root of a tooth, about three-fourths of an inch long, was extracted from the left nostril. At one end there was some calcareous matter firmly adherent. The nasal symptoms soon subsided.

CASE II.[1]—Mary F——, aged eight, applied for treatment to the Throat Class of the Roosevelt Dispensary on August 17, 1888. Her father died of phthisis. The child was undersized, and had evidently been a sufferer from rachitis. The mother could give little or no previous history of the case, except that the child's nose, as far as she knew, was in a normal condition when she was a year old. Since then the nose had been stopped up so as to prevent nasal breathing. There had been considerable offensive discharge. The bridge of the nose was sunken. The nostrils were flattened and contracted. The superior alveolar process on the left side, corresponding to the situation of the incisor and canine teeth, was absent, leaving a slight cleft. No history of accident could be obtained, the mother stating that she had never noticed the defect before. The left nostril was obstructed by a foreign body, which gave a grating sound on the impingement of a probe. Considerable force was necessary to extract it with the forceps. It was found to be the crown of an incisor tooth. It was notched, as in young children, and larger than in a child a year old. There was considerable calcareous matter around it and in the nostril, but no root was found.

The patient's nasal symptoms had very markedly abated at the next visit, and since then she has not been seen.

---

ADMINISTRATION OF COD-LIVER OIL.—It is stated by a French physician that a mixture of equal parts of cod-liver oil and lime-water, makes a fairly palatable and permanent preparation. It may be flavored to suit the taste.

## TUBERCULOUS PULMONARY ANEURISM—RUPTURE—DEATH IN EARLY STAGE OF THE DISEASE.

By J. W. KIME, M.D.,
FORT DODGE, IA.

On the morning of September 1, 1889, I was called to see Mrs. R. M. W——, aged forty-two, married, mother of four children, two dead, one of diphtheria, the other of consumption. Patient's mother died of asthma (?), probably phthisis, at the age of sixty-one. Other family history fair. Daughter died in 1888, at the age of fourteen, of phthisis.

During daughter's illness, in 1887, Mrs. W——'s temperature constantly ranged from 99½° to 100½° F., but she would not consent to further examination at the time.

On July 13, 1889, her fourth child was born after a normal pregnancy and labor. Health since 1887 to birth of child has been exceptionally good, and average weight six to ten pounds greater than in former years. After labor she felt stronger and better than after other pregnancies, and in three weeks attended her household duties.

On August 31st she had a slight pulmonary hemorrhage, on account of which I saw her on the following day.

Examination shows very slight dulness, and coarse râles at apex of right lung. At two inches to the right of the sternum, in the third and fourth intercostal spaces, there is a well-marked aneurismal bruit. Temperature, 99° F.; pulse, 100. No cough or expectoration at any time; feels quite well, and is at work.

On September 4th a second hemorrhage occurred, about one ounce of blood being expectorated.

On September 7th a hemorrhage took place early in the morning, and again in the afternoon of the same day, when about four ounces of blood were expectorated, and the bronchi were nearly filled, so that patient became almost asphyxiated; rallying, however, she rested quietly till 6 A.M. the following day, when a hemorrhage, proving fatal in a few minutes, occurred. The aneurism had evidently ruptured the previous day, but a plug forming, checked its flow until it became displaced, when fatal hemorrhage ensued. At this time, less than a half ounce of blood was expectorated; the bronchi filled with blood, resulting in death from asphyxia.

The tuberculous process could not have extended to any considerable degree in this case, but was confined to and about the walls of the vessel, which finally gave way.

## ANTIPYRIN IN LABOR.

By J. BARAN, M.D.,
NEW YORK.

This drug, to be given by rectal injection, has been lately recommended for the relief of severe pains of labor. It had been my intention of using it in that way, but found no occasion for it in the cases presenting the last few months.

Administering the drug in one of my last cases, and observing the most striking beneficial results, I thought it proper to bring it to the notice of the profession. Mrs. S——, aged about twenty-two, primipara, had suffered labor pains almost continually from the morning of August 24th to the afternoon of August 29th. She claims to have suffered most acutely, crying for pain, so as to compel the administration of doses of morphia, with only trifling results. The first dilatation of the os was perceptible on the morning of August 28th, and increased very slowly. On the 29th, about four o'clock P.M., the woman suffering agonizing pains, dilatation about one and a half inch in diameter, great rigidity of the cervix, I ordered twenty grains of antipyrin by the mouth, which she took about half an hour later. When seen again, one and a half hour after, I found the second stage of labor fully established. She made powerful expulsive efforts. I was prepared with chloroform, having felt certain there would be necessity for it, but to my astonishment, she assured me that she did not mind the pains at all, that they were very trifling, and very easily borne. She gave birth, half an hour later, to a very large baby. The striking symptoms were immediate great relaxation of the rigid os, and the almost entire absence of suffering during most powerful expulsive efforts after one dose of twenty grains antipyrin, given by the mouth.

## AN IMPROVEMENT IN THE TECHNIQUE OF INGUINAL COLOTOMY.

By CHARLES B. KELSEY, M.D.,
NEW YORK.

In the last few inguinal operations I have performed, I have adopted the following plan: The incision is that of Crips—across a line from the anterior-superior spinous process to the umbilicus. After getting the sigmoid flexure outside the body, a hair-lip pin is passed under it in the following manner: It is entered through the skin on the side of the wound toward the median line, and at the junction of the lower with the middle third of the incision. It perforates first the skin, next the parietal peritoneum, next the mesentery of the gut close to the bowel, and at the junction of the lower and middle thirds of the exposed loop, next the parietal peritoneum on the other side of the incision, and finally, the skin. By this means the gut is so firmly held in position that it cannot be dislodged by any vomiting, and a perfectly satisfactory spur is formed, which will prevent any passing of fecal matter beyond the opening. After this procedure I have never been troubled either by prolapsus of the mucous membrane, or the passage of fæces from the colon into the rectum. With this modification I now adopt a running suture instead of about fourteen interrupted ones, to join the parietal peritoneum to the visceral layer, and to the skin. A rapid operator can easily, in this manner, complete the entire technique of inguinal colotomy in ten minutes, and to this extent reduce the necessary shock.

25 Madison Avenue.

## AN IMPROVED WAY OF USING THE HYPODERMIC METHOD.

Dr. P. G. Udell, of Spencerport, N. Y., writes: "Every physician who employs the hypodermic method is aware of the fact that painful swelling and abscess not infrequently follow its use. This undoubtedly arises from the introduction of septic matter—because the method of antisepsis has not been rigidly applied to this simple surgical proceeding. The sources of infection are numerous. The syringe may be unclean; the needle may be foul; the hypodermic tablet may be composed of materials that undergo fermentation; the water used as a solvent may be impure; the spoon employed to prepare the solution in may furnish the septic matter, etc. I have for some time used a method whereby the above dangers may be positively avoided. In one of the compartments of my syringe-case I carry two small test-tubes, nested; the inner one is converted into a vial by closing the open end with a cork, and contains my hypodermic needles immersed in absolute alcohol. This agent sterilizes any septic matter that may be on the needles, and does away with the necessity of using a wire for maintaining the patency of the same; there is no rusting, and the needle is always aseptic. I frequently cleanse the syringe with a five per cent. carbolic acid solution. Having occasion to use it, I free the needle of alcohol by passing through it water that has been boiled. I now dissolve one of Wyeth's tablets in a few minims of boiled water, and for this purpose carry the second test-tube, in which water may be boiled quickly over any flame that may be convenient, a match answering the purpose very

well. After the solution is sufficiently cooled, it is drawn into the syringe, and is ready for use. The above plan may seem somewhat fussy in detail, but in practice is exceedingly simple, and, if followed as directed, should relieve the physician of those mishaps so annoying to himself and patient. If some instrument-maker will materialize this idea, it will involve but slight increase in size of the pocket-case now in use."

## LATE PREGNANCIES.

DR. J. R. N. SMITH, of Milltown, Me., writes: "In accordance with your request for reports of late pregnancies, I can report one in my early practice. February 14, 1868, Mrs. K——, in this State, then being fifty-two years of age, was delivered of twins. Her youngest child was ten years of age. She had had (I think) eight children before, all living."

# Progress of Medical Science.

THE RESEMBLANCE OF THE MALARIA PARASITES TO THOSE OF FEBRIS RECURRENS.—N. A. Sacharoff states that there exists in the blood of patients suffering from febris recurrens a hæmatozoon which may be best observed immediately after the temperature begins to fall, and which then assumes enormous proportions (twenty and more diameters of a red blood-corpuscle) (*Centralblatt für Bakteriologie und Parasitenkunde*). But specimens of lesser size are also found. The parasite consists of a delicate amœboid body containing a multitude of dark, round, uniform, sharply outlined movable granules. Besides these the protoplasma contains a generally grayish, homogeneous nucleus as large as one or two red blood-corpuscles. The protoplasma sends forth pseudopodia (without granules) which sometimes separate from it and appear as small, delicate pieces of protoplasma without granules. They vary in size and are often swallowed by red blood-corpuscles, in which they gradually grow and finally develop into the above-mentioned large amœboid body. In a description contained in the "Minutes of the Session of the Caucasian Medical Society," in Tiflis, Sacharoff designates the large protoplasma lumps described by Ponfik as his parasite, Hæmatozoon febridis recurrens. He declares that the granules in the protoplasma which Ponfik took for granules of fat are mostly pigment, not fat. From time to time the protoplasma itself sends forth pseudopodia in which no granules are to be found; these pseudopodia fall off and circulate freely in the blood. By separating from the protoplasma, however, the parasites become smaller, until finally only the nucleus and a narrow zone of protoplasma containing granules remains. The nucleus itself is round, delicate, grayish, also reddish, and Sacharoff thinks that it is merely a red blood-corpuscle. The nucleus sends forth pseudopodia, or buds, which separate from it and also circulate freely. Sacharoff watched such separated speusodia and noticed successive changes in them, *i.e.*, he saw spirochætæ-shaped threads form from nucleus-pieces within from eight to ten hours. They did not show any small undulations and were not very thin, but large undulations were distinctly visible. He thinks this is possibly the genesis of spirochætæ. Nor do the lumps separating from the protoplasma remain without further development. They have a motion of their own, attach themselves to red blood-corpuscles, send buds into them, and finally are completely enveloped by them. Here they may assume various shapes and may grow larger and gain granules of pigment in the protoplasma. They distend also the blood-corpuscle containing them, and seem to be able to cause its disappearance. On the other hand, they can emigrate with equal facility from the blood-corpuscle. Then the parasite becomes free and continues to grow, or decomposes, as was shown above. Immediately after the crisis the three first-named forms exist in large numbers; further on, during apyrexia principally or exclusively, the intracellular forms are to be found. This is the main difference between it and the plasmodium malariæ where the intracellular forms are found only during the fever. This report is very important, and it opens new points in the etiology of this disease. If the highly interesting discoveries of Sacharoff should be confirmed, we should have reliable means for the diagnosis of the disease during apyrexia, as the intracellular forms, which can be stained with meythl blue (at least in intermittens), are easily seen. In uncolored specimens they are hard to see. The same peculiarity might then be utilized as a means of differential diagnosis from intermittents, with which febris recurrens is easily confounded.—*The Journal of the American Medical Association.*

STROPHANTHUS AS A LOCAL ANÆSTHETIC.—Many of the drugs which are useful in the treatment of cardiac disease also possess a local anæsthetic action. There is, of course, no connection, as far as can be seen at present, between the two actions. The local anæsthetic action of erythrophleine was investigated last year by many observers; the conclusions arrived at were that, although it possessed a powerful local anæsthetic action, it causes irritation and dilatation of the vessels of the conjunctiva, and in some cases even severe inflammation. It was thus much inferior to cocaine, whose action is accompanied by a constriction of vessels and consequent pallor of the part. Helleborin, the glucoside from the Christmas rose, is also a local anæsthetic and cardiac tonic; one-fortieth of a grain in solution placed on the conjunctiva of a rabbit causes complete anæsthesia in fifteen minutes, and there is at the same time no interference with the movement of the pupil and no dilatation of vessels. The action of this glucoside is therefore like that of the alkaloid cocaine; but it has not yet come into general use. Steinach has lately shown that strophanthus seeds contain a body not identical with strophanthin, which when placed on the conjunctiva produces in twenty-five to thirty minutes complete anæsthesia, lasting from two to twelve hours. There are no great signs of irritation, but if applied to the eye of man it causes a slight feeling of burning, with a passing hyperæmia of the conjunctiva. This condition may pass on to cloudiness of the cornea in animals. The local anæsthetic action of strophanthus is, therefore, chiefly of pharmacological interest, like that of erythrophleine. Cocaine still holds its own when judiciously employed.—*British Medical Journal.*

EXALGINE, THE NEW ANALGESIC.—Exalgine is the name given to a new derivative of the aromatic series, orthomethylacetanilid, discovered by Brigonnet, of the Cochin Hospital, and which has suddenly leaped into extraordinary favor as an analgesic in France (*St. Louis Medical and Surgical Journal.*) The name (*ex*, privative, and *algos*, pain) is significant of its qualities. The formula is $C_9H_{11}NO$ (or $C_6H_4.C_2H_2O.NCH_3$), and the substance is one of the three isomeric (para, meta, and ortho) methyl derivatives of acetanilid. It occurs either in fine acicular or long tablet-like crystals, accordingly as it is obtained by evaporation from solution, or by fusion thereafter. It is sparingly soluble in cold water, more soluble in hot water, and extremely soluble in very dilute alcohol, or in water slightly alcoholated. Physiologically it acts very much like analgesine, having, however, more effect upon the sensory and less upon the thermogenic centres than this substance. Its therapeutic effects are obtained in doses of from four to six grains, administered at once, or from six to twelve grains taken in two doses in the course of twenty-four hours, and are powerfully analgesic, subduing the element of pain in all forms of neuralgia, including visceral. Like all new remedies of this sort, it is at present on its good behavior, as it were, and it is claimed by MM. Dujardin-Beaumetz and G. Bardet that it has in their hands up to the present ex-

hibited no evil sequelæ, being free from the rash, cyanosis, etc., so frequently observed after the ingestion of antipyrin and acetanilid. Exalgine is eliminated by the urine, upon the quantity of which it exercises a marked effect, acting like the antipyretics of the same group, diminishing the quantity of the secretion. In diabetes it also diminishes the quantity of sugar eliminated. Like all of the derivatives of the aromatic series, it is antiseptic and antithermic, as well as analgesic, and possesses the latter quality in a comparatively superlative degree, being more efficient, in doses less than half so great, than antipyrin. The following are the formulæ for its exhibition, as given by M. G. Bardet in *Les Nouveaux Remèdes*.

1. *Antineuralgic potion of Exalgine.*

| | |
|---|---|
| ℞. Exalgine | ʒ j. |
| Kirschwasser | ʒ x. |
| Simple syrup | ℥ j. |
| Distilled water ..... q. s. ad | ℥ v. |

Dissolve the exalgine in the kirsch water and add the syrup and water. The dose is from one to three tablespoonfuls in the course of the day.

2. *Solution of Exalgine.*

| | |
|---|---|
| ℞. Exalgine | ʒ i. |
| Rum | ʒ x. |
| Distilled water ..... q. s. ad | ℥ v. |

Proceed as before. The dose is the same as above.

The Mortality Among Nurses.—The question as to the liability of nurses to infection while in attendance on phthisical patients is an important one, and has not hitherto been studied with the attention it merits. The result of a careful inquiry into the increase in Germany, where the nurses are largely drawn from religious corporations, shows that while the mortality from tuberculosis among the sisters who remain in the convent is from one-seventh to one-sixth of the total mortality, among the nursing sisters the proportion amounted to nearly two-thirds. The death-rate from tuberculosis among the nursing sisters attains its maximum between the thirtieth and fortieth year, and then steadily declines. Compared to the deaths from this cause among the population of the towns in which they live, the mortality from all causes among nurses between the ages of fifteen and twenty is four times as great as outside, between twenty and thirty three times as great, and from thirty to forty twice as great, the explanation being the prevalence of tuberculosis among nurses, the death-rate from this source alone being nine times as great as among the general population. Infectious diseases levy an excessive tribute on nurses up to the age of forty, after which time deaths from this cause become infrequent. It appears, moreover, that nurses enjoy comparative immunity from infection during the first six months' service, but the proportion of disease and death then rises steadily for three years. Of course the figures only represent an average, and do not apply to particular hospitals and institutions, the hygienic conditions of which necessarily vary very considerably. A return drawn up upon reliable data would be of very great advantage from several points of view, and perhaps it may, at some future time, be forthcoming.—*Medical Press and Circular.*

The Cocoanut as a Tæniacide.—Professor Parisi, of the University of Athens, accidentally made the discovery recently that the cocoanut possesses anthelmintic properties. He ate the fruit of the nut after having drank the milk. Two hours later he began to feel somewhat nauseated and had a slight diarrhœa. The following morning he passed at stool a dead tape-worm with its head. He was then in Abyssinia and inquired of the natives whether they made use of the cocoanut for this purpose, but none of them had ever known it to be so used. Upon Dr. Parisi's return to Athens he used the remedy in a number of cases and found it very efficacious. It is preferable to other tæniacides, he says, in that no preparatory treatment is necessary. In all cases the entire worm, including its head, was passed at stool on the morning following the administration of the cocoanut.—*Schmidt's Jahrbücher.*

A New Form of Suture Button.—At a recent meeting of the Ontario Medical Association, Dr. M. A. Powell exhibited a suture button which he had devised. It consists of an oval plate of block tin, about five-eighths by seven-eighths of an inch in size, from which arises a central post three-sixteenths of an inch in height. This post is perforated with a round hole from the under surface of the plate to its own apex and is cross-cut down nearly to the plate. In using the button the suture, of wire, silk, or catgut, is passed through from below, bent into the slot, wound two or more times around the post and then carried across the post through the slot again. The buttons can be readily sterilized by boiling and can be bent to fit irregular surfaces. They can, Dr. Powell says, be instantly fastened, unfastened, tightened or relaxed, and cannot slip or break.

Tobacco and Insanity.—The essay recently read before the San Francisco Medical Society by Dr. Shiels, on tobacco and its effects, was one deserving of exceptional credit, as well for the thoroughness of his investigations as for the general fairness of his conclusions. The doctor addressed a series of questions to the members of a leading New York medical society individually, and upon their answers his deductions are mainly based. The general trend of the decisions of this medical tribunal is that smoking in excess is bad, which few will be found to dispute. The question, "Have you ever seen a case where the brain was permanently affected by the use of tobacco?" elicited a symphonious chorus of noes all along the line, disturbed only by the solitary demurrer of an exasylum superintendent, who claimed five cases of insanity due to the weed. Dr. Shiels believes there must have been some error of diagnosis here, and beyond a doubt the large majority of asylum physicians would, if canvassed, sustain him in his skepticism. It is only in a remote and subsidiary sense that the tobacco habit can be considered a factor in the production of insanity. Its opponents urge that it promotes nervousness. This depends on the individual and the amount indulged in. They also claim that it weakens moral fibre, impairs nutrition, fritters away a man's time, and induces a host of other evils. But it is not upon the brain that the penalties of its immoderate use are visited; the organs more likely to suffer are the heart, stomach, and throat.—*Occidental Medical Times*, July, 1889.

---

The Foods of Different Peoples.—Many nations, many dishes! Some articles that are esteemed as delicacies by certain nations are regarded with disgust by others. According to the *Pacific Record* the Turk is seized with violent trembling at the very idea of eating oysters. The American Indians look upon an invasion of grasshoppers as a mark of especial favor from the Great Spirit, and make the best of such a time to lay up a store of provisions for the future. Buckland states that among certain people a mixture of fish, nearly putrefied, and soap-suds is preferred to the best butter. In Canton and other Chinese cities rats are sold at ten cents a dozen, and a hind-quarter of dog is more expensive than mutton or beef. Some of the East Indians eat serpents dried in the oven, but despise the flesh of rabbits. Lizard eggs are a delicacy in the islands of the Pacific, and many people besides the aborigines of the Argentine Republic esteem the flesh of the skunk. Ants are eaten by many peoples, and in Siam a curry of ants' eggs often tickles the palates of the wealthy. The silk-worm is eaten with relish by the Chinese, and a dessert of roast snails is considered a fitting termination of a feast in New Caledonia.

# THE MEDICAL RECORD:

## A DISCUSSION ON THE QUESTION OF MEDICAL EXPERTS.

THE vexed question of medical expert testimony was brought up at the recent International Congress of Forensic Medicine in Paris, and was discussed and settled in a most interesting way. The gentlemen concerned in the debate included some of the best criminal lawyers and judges in Paris, as well as several physicians eminent in medical jurisprudence.

The subject was opened with a report drawn up by MM. Adolphe Guillot and Demange, both Judges of Instruction.

It must be remembered that in France, in the case of criminal trials calling for medical or toxicological experts, a commission is appointed to whom the scientific investigations are referred. The report of this commission, being presumed to be impartial, necessarily carries great weight; and if it is against the accused, it is almost a fatal blow to his case.

Although, theoretically, the method seems fair and proper, yet, practically, it has acquired unpopularity because it seems to have worked unduly against the accused. The gentlemen above referred to seemed inclined to yield to this popular current of opinion, and recommended, in general terms, that there be a list of experts made out by the State, from nominations made by learned bodies. Then it was advised either that the prosecution and defence each select its own expert, or that the judge appoint two experts, leaving the defence the right to object to one of them. The experts should have the same sum each, and should be paid by the State. In case the experts disagreed the case should be referred to a court of appeal.

The views of the Congress upon these suggestions were shown in the vote upon the nine different recommendations of the reporters.

The first, to the following effect, was carried unanimously: "To guarantee the interests of society and of the accused in all medico-legal investigations, at least two experts shall be employed." The next sentence, "These shall be appointed by the judge," was carried by a small majority, for a large minority voted in favor of each side appointing its own expert. A resolution giving the defendant the right to object to one of the experts was lost. The Congress next voted: "That experts, except in special cases requiring special knowledge, shall be chosen from lists drawn up by the public powers and the scientific bodies selected for that purpose. The system of the plurality of experts imposed the constitution, at the seat of the Faculties of Medicine, of a Supreme Council of Forensic Medicine, which should act as a high and final Court of Appeal." With respect to this latter resolution, it was pointed out that a similar institution had worked very well in Germany. At first there had been many cases referred to this court, but in a short time it was found to act as an excellent check against careless investigation, and now the cases sent up on appeal were not at all numerous. The Congress then carried the following resolutions without any further discussion and without any opposition: "That the Judge of Instruction should be present at the post-mortem, etc., except in special cases, so as to supply to experts such information as may guide their researches; and that the lawyer retained for the defence may also be present, so as to point out to the experts the objections the defence may raise."

It was also advised that in law schools there should be classes in criminal law, and that students should be admitted when possible to post-mortem examinations.

## THE MEDICAL PROFESSION AND THE WORLD'S FAIR.

THERE is, so far as we can learn, as yet no representation of the medical profession upon the World's Fair Committee appointed by the Mayor. All the various trades and business interests have one or more members, and there are plenty of lawyers and journalists. It would seem but just that medicine should also be allowed to take an active interest in an event which promises to be memorable in our civic history.

As the purposes of the Fair have so far been outlined, there will surely be a field for medical and surgical displays of various kinds. There should be historical exhibits to show the progress in the care of the sick, and in their surgical and medical treatment, with displays illustrating the old hospitals and the new, the old surgical instruments and mechanical appliances and the new. There should be illustrations also of the development of the specialties, with displays of all new apparatus and instruments of precision in every field. The development of bacteriology, the improvements in methods of teaching, historical accounts of medical progress, and of the growth of sanitary science, all would have a fitting place.

It is easy to see that a medical and surgical exhibit might be made which would have great intrinsic interest, and would be of immense educational value, not only to the medical profession, but to the laity.

We trust that some steps will be taken soon to see that the medical profession be given its share of the work.

## ELECTRICITY IN GYNECOLOGY.

THE discussion over the value of electricity in pelvic disorders still continues, and the views of gynecologists still remain far from settled. The method, outside of Paris, has chiefly been tried in Great Britain and the United States. In the former country such eminent authorities as Sir Spencer Wells, the Keiths, and Dr. W. S. Playfair are inclined decidedly to favor Apostoli's method, while Mr. Tait and Mr. Bantock are as decidedly against it. In this country no one very prominent as a gynecologist

has, so far as we know, undertaken to champion electrolysis, but a number of men of excellent repute have reported their results, and have as a rule spoken favorably of the method. Useful contributions to the technique have also been made by Martin, Goelet, and other American physicians.

It is evident, from the tone of discussions upon the subject, that the older gynecologists, while not favorably disposed toward Apostoli's method, have not tried it to any great extent.

There seems to be a tendency to use milder currents than were formerly advocated, and a thirty-cell battery is even stated to be amply sufficient for all purposes. It seems, therefore, that a maximum current of one hundred milliampères may often be all that is needed; while we hear little now of the eight hundred and one thousand milliampère currents about which discussion was first raised.

Dr. A. Lapthorn Smith, of Montreal, has recently given an interesting account of his experiences with Apostoli's method (*American Journal of Obstetrics*). Dr. Smith has abandoned punctures, and relies upon the intra-uterine applications, using not very strong currents, apparently not much over one hundred milliampères. He reports cases of endometritis, perimetritis, and fibroids cured or greatly relieved. No exact rules can be given as to the frequency and number of applications, or the strength of the current. The use of the positive pole in hemorrhagic conditions is approved by him, as by all others. It seems, indeed, that a relief of menorrhagia is one of the things which it is agreed electricity can accomplish. Ovarian pains also are often cured. The exact effect of the currents upon fibroids is yet an unsettled point. They certainly often decrease in size under treatment, but whether there is a true electrolytic action is yet hardly demonstrated.

It is noticeable that most of the older men who have worked successfully with the knife are inclined to stick to the tools they have been handling. But evidence is accumulating which makes it apparent that there are many cases in which hysterectomy or ovariotomy ought not to be performed before an electrical treatment has been tried.

## THE BLOOD-VESSELS OF THE LUNGS.

Some time ago we asserted editorially that the blood-vessels of the lungs had practically no vaso-motor nerves. This statement was based chiefly on the fact that the presence of such nerves had never been positively demonstrated in mammals by physiological experiments; and also on the well established fact that the pressure in the pulmonary circulation is very little influenced by nervous stimulation, or by the changes in the heart's activity, such as affect the systemic circulation. It is equally known that the tonus of the pulmonary arteries is very slight, while the vessels are very yielding and distensible. The result is that a complete obstruction of a large pulmonary vessel hardly changes the blood-pressure in the lungs at all, owing to the easy relaxation of the vessels elsewhere.

It is a fact, therefore, still holding good, that the pulmonary blood-vessels are but feebly influenced by vaso-motor nerves.

The actual presence of these has, however, been quite recently demonstrated by Drs. J. R. Bradford and H. Percy Dean (*Journal of Physiology*, vol. x., Nos. 1 and 2). These experiments were made upon dogs, and resulted in showing that vaso-constrictor nerves originate in the medulla, pass down the spinal cord, make their exit from the second to the seventh dorsal segments, and pass to the arteries of the lungs. Stimulation of them causes a slight rise in pulmonary blood-pressure, but their influence is not strong.

The use of a drug like ergot in hemorrhage from the lungs has therefore not much support on physiological grounds.

## THE PURPURAS.

Purpura is a name given to a class of disorders of the most varying origin, and presenting the most divergent types. The result is that systematic writers upon purpura have, as a rule, treated the subject in a tentative and uncertain manner, giving classifications and descriptions which were admitted to be mainly provisional in character. Under the general head of purpura, one finds subdivisions of purpura simplex, purpura rheumatica or peliosis rheumatica, purpura hæmorrhagica. We have, besides, purpura nervosa or myelopathic purpura, purpura urticans, purpura papulosa, purpura scorbutica, or scurvy, and the various cachectic, senile, infectious, and mechanical purpuras.

From all this it may easily be seen how little of definite significance the term purpura possesses. In the attempts at classifying its types we may abandon at once the divisions into idiopathic and symptomatic, for it can safely be said that purpura is always symptomatic of some profound nutritional or mechanical disturbance. We can also exclude from the ordinary purpuras the purpura scorbutus, since that is a well-defined malady of quite well-known origin. The three types of purpura which are most commonly seen in this country are probably the purpura simplex, purpura rheumatica, and hæmorrhagica, and certain cachectic forms occurring in alcoholic and debilitated subjects. The simple purpuras include those mild types observed oftener in the aged, and not associated with much articular or gastro-intestinal disturbance. There is difficulty in really separating the types known as purpura rheumatica and purpura hæmorrhagica. There are intermediate forms which show that the disease has the same general origin. In the purpura hæmorrhagica the mucous membranes are more profoundly involved; in purpura rheumatica, it is the joints. In a recent brief paper by Dr. William A. Edwards, on "Some Forms of Purpura Rheumatica" (*University Medical Magazine*, September, 1889), illustrations are given of three types of purpura rheumatica described by Osler. From the description of cases given it would seem quite justifiable, however, to give up the term purpura rheumatica altogether, and include all the different severe forms under the general title purpura hæmorrhagica. These may then be further qualified by the terms arthritic, or gastro-intestinal, or mixed. The attempts to make of purpura a nervous disorder (Couty, Henoch, Faisans) have not been very successful, although purpura, like urticaria and œdema, may no doubt, at times, be the result of nervous influences; but where there are severe hemorrhages and ecchymoses, a deeper disturbance of nutrition must be invoked.

The belief has been that the cause of the purpura directly was a poison developed through some fault in chylopoëtic metabolism, and this is no doubt generally the case. But efforts have been numerous to place the disease among those of microbic origin. Micrococci have been found by competent observers in the ecchymotic spots, and Guimand (*Paris Médical*, September 8, 1888) has succeeded in making pure cultivations and inoculating rabbits, with the result of producing purpuric eruptions.

## News of the Week.

THE MEDICAL SCHOOLS OF THIS CITY all report unusually large accessions of students.

JEFFERSON MEDICAL COLLEGE.—The Jefferson Medical College and Hospital, Philadelphia, will soon add a new building to the group already located at Tenth and Sansom Streets.

A MATERNITY HOSPITAL.—A Maternity Hospital has just been added to the other clinical facilities of the Medical Department of the University of Pennsylvania.

UNIVERSITY OF MICHIGAN.—The *Boston Medical and Surgical Journal* states that the regents of the University of Michigan, at Ann Arbor, have received an offer of two acres of land for a hospital site from Mrs. Israel Hall.

AN ANTI-VIVISECTION HOSPITAL.—The *Zoöphilist* states that there will shortly be established in London an anti-vivisection hospital.

A DISPENSARY IN PARIS has just been built by the jewels of a lady named Madame Edouard André. The jewels were given to the Philanthropical Society, and were sold for $80,000.

A STATUE has just been erected at Auxerres, of M. Paul Bert, and one at Alfort, of the distinguished veterinarian, the late Professor Bouley.

A DISPENSARY LOVE-FEAST.—About twenty physicians attached to the Northern Dispensary held a social reunion at Clark's a few nights ago.

DEATH OF ALBANY PHYSICIANS BY DROWNING.—Dr. Otto Ritzman, of Albany, was drowned at Carrying-Place Bay, Lake Champlain, August 19, 1889, in consequence of the capsizing of a boat in which he was fishing with Dr. William H. Murray and a guide. Dr. Ritzman was born in Albany in 1857, and was graduated at the Albany Medical College in 1879. This is the fourth Albany physician who has been drowned within a few years: Dr. J. V. Lansing, drowned May 9, 1880; Dr. H. I. Fellows, August 29, 1881; Dr. John S. Delavan, August 7, 1885; Dr. Otto Ritzman, August 19, 1889.

GETTING UP FOR MEDICINES AT NIGHT.—Innumerable mistakes have been made through persons getting up at night to take or administer a dose of medicine. We have heard of few sadder accidents, however, than that recorded of the wife of a well-known physician of Harlem. She had been suffering from insomnia, and got up to take a dose of bromide which she had been accustomed to use. By mistake she swallowed the contents of a bottle of Majendie's solution of morphine, taking sixteen grains of the drug altogether. Despite every effort she died in three hours.

CLARK UNIVERSITY has established the rank of "Docent" as "its highest annual appointment."

THE GERMAN DERMATOLOGICAL SOCIETY.—The next annual meeting of this society will be held at Berlin, in connection with the International Medical Congress. Professor Caspari, of Königsberg, has been appointed President; Professor Neisser, of Breslau, Secretary; and Professor Lipp, of Graz, Treasurer, for the year 1889–90.

THE REPORT OF THE STATE BOARD OF HEALTH on the water-supply of New York City has been made to the Governor, and its details made public. It is a most exhaustive study of the subject, and will be a document of great value in studying the problems of water-supply in cities. The investigation was made under the direction of Professor C. C. Brown and Emil Kuichling, engineers, with the assistance of chemical experts. A full survey of the Croton water-shed, with a detailed description of all the sources of pollution, natural and artificial, is given. It is shown that the Croton water is naturally of pure character, and all the sources of its infection or pollution being now known the problem of keeping the water pure is much simplified.

THE NEW LAW REGARDING PRELIMINARY EXAMINATION OF MEDICAL STUDENTS.—The imperfections in this law were pointed out by us when its provisions were first made public. The chief defect lies in the fact that it requires applicants for matriculation who come from foreign countries or other States to undergo an examination even if they come with certificates or diplomas from institutions of learning. The examination in English is also unfair to students from foreign countries, who may be well educated in their own tongue but know English imperfectly. The Council of the University of the City of New York has appointed a committee to formulate suggestions as to necessary amendments.

SPONTANEOUS COW-POX IN ITALY.—The Animal Vaccination Committee of Milan has recently had a windfall in the form of a supply of lymph derived from a herd of cattle in which cow-pox had spontaneously broken out. On August 3d the Prefect of Sondrio (Northern Italy) announced that natural cow-pox had appeared in a herd in the commune of Cosio, in Valtellina, at a height of 2,000 metres, near the top of the Tagliata Alp. The eruption had shown itself on the udders on June 27th, and of the eighty cows only four had not been attacked.

RUBBER BANDAGES IN INDIGESTION.—Dr. Wettendorfer, while using a Martin's rubber bandage, applied round the waist in a case of chronic eczema, became aware that this treatment seems to be capable of acting beneficially on the digestive organs, curing gastric catarrh and the sense of oppression complained of by dyspeptics, and, as a result of this action, improving in a marked degree the digestive functions. How the bandage acts Dr. Wettendorfer is unable to say, further than that he supposes it is by exerting a mechanical pressure on the organs of digestion, and possibly by causing the bodily heat of that region to be retained. As to the particular classes of cases in which the rubber bandage is suitable only further experience can decide. The bandage should be worn for about an hour after meals, and should be applied over a surface about ten inches in depth.—*Lancet.*

Bogus Diploma Mills Again.—Some months ago a practitioner of Buffalo presented as the evidence of his medical education a diploma issued by the "Trinity University of Burlington, Vt.," an institution of learning of which the very existence was unknown to the physicians of Burlington or to the Secretary of State. A "Dr." Bradbury, of Nashua, N. H., was discovered to be the agent of the university; and from him a hardware dealer of Buffalo succeeded in obtaining a diploma for the sum of sixty dollars, without any medical qualification whatever. It seems that all that is necessary to incorporate such an institution in Vermont is to make application to any town clerk for articles of incorporation, and they are granted forthwith. "Trinity" was found to have been incorporated in the town of Bennington, and a copy of the articles of incorporation is published in the Boston *Herala*. There was also discovered at Rutland a document incorporating the "Vermont Medical College or Second Medical College of the American Health Society for Scientific and Benevolent Purposes." Articles of incorporation of the "University of New Hampshire" were also discovered in the Secretary of State's office at Concord, bearing date of October 10, 1888.—*Boston Medical and Surgical Journal.*

The Prussian Chambers of Physicians.—For the second time since the establishment of the Prussian Chambers of Physicians their representatives have been invited to take part in the deliberations of the highest medical official body in Prussia, viz., the Scientific Deputation for Medical Affairs. At the time when the said Chambers were organized, the State granted them the right to be heard by the official authorities on certain general sanitary questions. Each chamber therefore received the right to send one representative to the Scientific Deputation, and one to the chief medical official body of its province, and these representatives are permitted to take part in the deliberations, but not to vote. They are now regarded as extraordinary members of the Scientific Deputation, and are invited to take part in its deliberations once every year, viz., in November. The themes of discussion this year are to be the reform of the midwife system, and the revision of the official text-book for midwives. These subjects will be introduced by Professors Olshausen, of Berlin, and Bockendahl, of Kiel.—*Lancet.*

How to Inhibit Whooping-cough Paroxysms.—In the *Correspondenzblatt für Schweizer Aerzte*, No. 14, 1889, p. 417, Dr. O. Naegeli, of Ermatingen, describes a new purely mechanical method for treatment of whooping-cough. Given a paroxysm, the author, standing in front of the patient, firmly catches the ascending rami of the lower jaw with his forefingers, and middle fingers placed just in front of the lobes of the ear, places his thumbs on the chin, and, by strong and steady traction and pressure, pushes the jaw forward and downward. The procedure may be very conveniently modified by making traction with the right thumb and forefinger placed on the alveolar process behind and below the middle lower incisors, and the remaining fingers under the chin, while the left hand is fixed on the child's forehead for purposes of counter-traction. If the patient stands with his back to the operator, the latter places his thumbs just above the angle of the lower jaw in front of the ears, the forefingers on the zygomatic arches, the remaining fingers on the chin, and then pushes the jaw forward and downward. Traction may be made still more rapidly by putting the forefingers into the patient's mouth, on the alveolar process behind and below the back molars. No force should, of course, be applied to the child's teeth. As soon as the jaw has been moved in the way indicated, the patient is told to inspire deeply. The procedure is said to cut short the spasm almost instantly, which effect is explained partly by its diminishing the muscular tone in a reflex way, partly by its mechanically lifting up the epiglottis (through raising the larynx with the hyoid bone) and opening the rima glottidis. A systematic inhibition of the paroxysms by means of the manipulations has a markedly favorable influence on the course and issue of the disease. The disease becomes milder, vomiting ceases, expectoration greatly lessens, hemorrhages, as well as complications caused by increase in the arterial tension during the spasmodic attacks, are prevented all through, and the total duration of the affection is shortened, while all bad after-effects are avoided. The same manipulations also give admirable results in spasmodic cough of any origin. The method is very simple, and may be easily learned by nurses, mothers, etc. It is entirely painless, hence little patients subject themselves to it very willingly, and, even after having experienced the striking relief obtained therefrom, try to perform the manipulations on their jaw by their own hands.—*British Medical Journal.*

The Transmission of Gonorrhœa as an Indictable Offence.—The *Deutsch. Med. Zeit.* relates the following: A man was charged with rape by a fifteen-year-old girl, at Stein-am-Anger, but at the trial he was declared not guilty of the charge, as no force was employed. The testimony showed, however, that at the date of intercourse the man was suffering with gonorrhœa, and that afterward the girl also had gonorrhœa, and on this basis the prisoner was charged with inflicting severe bodily injury upon the girl, was found guilty, and sentenced to one month's imprisonment. The two higher courts approved this, but thought the punishment was too light; one court lengthened the term to six months; the other and highest authority thought it was still not enough, and increased the punishment to one year. While such a proceeding is very unusual, it is not unjustifiable, and should the example be followed the prisons would soon need enlargement. For obvious reasons there is no fear that such will be the case.—*Weekly Medical Review.*

Cholera in Asiatic Turkey.—Bagdad and Bussorah have, according to a correspondent of *The Times*, been visited by an epidemic of cholera. The disease was first noticed in obscure inland spots, whence it spread to the port of Bussorah, near the head of the Gulf of Persia.

Hospital for Vienna Students.—The Association for the Care of Sick Students at Vienna has purchased a house in the Laudongasse, at a cost of 55,000 florins, which is to be opened in the course of the coming academic year for the reception of students suffering from illness or injury. It is now being fitted up as a private hospital, with accommodations for forty patients. It is estimated that the cost of maintenance will be 15,000 florins a year

# Society Reports.

## THE PRACTITIONERS' SOCIETY OF NEW YORK.

*Stated Meeting, May 24, 1889.*

FRANCIS P. KINNICUTT, M.D., PRESIDENT, IN THE CHAIR.

DR. C. L. DANA exhibited some

### SPHYGMOGRAPHIC TRACINGS IN A CASE OF MARKED ABDOMINAL PULSATION.

The patient was a very nervous, delicate young woman, a factory operative, who had suffered from several attacks of a so-called malarial fever which is very common among the operatives along the East Side. The affection is called malarial, but it does not yield to quinine. After one of these attacks had subsided, the patient began to vomit and presented all the symptoms of an acute gastritis, and was treated for that. Before this, however, she had developed a very extraordinary pulsation, with bruit, in the abdominal aorta, which caused her much distress. No tumor could be made out on palpation. The vomiting was checked for a time by means of opium suppositories, but soon returned. After the gastric trouble began to subside, the speaker decided that the case was not one of gastritis but that the vomiting was largely hysterical. He persuaded the patient that she need not vomit again, and the trouble soon ceased.

Dr. Dana took some sphygmographic tracings of the abdominal pulsations and of the radial pulse. The former showed a number of serrated points at the apex, presenting evidence of a very extraordinary degree of arterial relaxation. Three days later, however, when the pulsations had subsided to a great extent, the point was a single blunt one. The pulsations were evidently due to a very marked dilatation of the aorta, and they are observed very commonly, the speaker had been told, in this peculiar form of fever. They had appeared in the same patient during a previous attack a year before the present one. There was an anæmic murmur audible over the heart, which disappeared as the patient got better. Dr. Dana thought the observations of some interest as showing positively a high degree of arterial relaxation; this being less as the pulsation was less. The pulsation was abdominal, not epigastric.

DR. WILLIAM M. POLK said this pulsation was often seen in nervous, hysterical women, even when there was no fever.

DR. BEVERLEY ROBINSON observed that pulsation of the abdominal aorta was not at all infrequent. So common was it, indeed, that it often caused considerable trouble in coming to a diagnosis in cases of suspected abdominal aneurism.

DR. WILLIAM H. DRAPER said that in febrile conditions, especially in children, marked epigastric and abdominal pulsations were frequently observed. He had always regarded them as due to arterial relaxation.

DR. ANDREW H. SMITH reported a case of

### PERIODICAL ENGORGEMENT OF THE LIVER,

occurring in a married woman, twenty-six years of age. There was no history of alcoholic indulgence, of syphilis, or of any special illness except that she had had malarial fever five years ago. She had had six children and no miscarriage. Since the birth of her last child, one year ago, menstruation had been scanty and somewhat painful. Three months before admission to the Presbyterian Hospital she missed her menstrual period, but had at that time chilly sensations followed by hot flashes, and severe pain in the right side. The side became swollen and was very tender. These symptoms persisted for about ten days, and then disappeared, but returned again at the next menstrual period with greater severity. This recurred each month, there being no menstrual flow, but its place being taken by the pain and swelling in the right side. The patient was admitted six days after the beginning of the third of these attacks. She was then suffering from nausea and vomiting, pain in the right hypochondriac region, and anorexia. The area of hepatic dulness was much increased at both its upper and its lower borders, extending from one inch below the nipple to a point about three inches below the free border of the ribs. There was great tenderness over this entire region, most marked, however, at a point about three inches to the right of the umbilicus. The spleen was also enlarged. Examination of the urine gave negative results. An exploratory puncture with a needle in the eighth intercostal space, on the right side, showed some bloody serum, and another puncture drew off some dark blood. Within a week after admission the liver had become reduced to its normal proportions, and the pain and tenderness had disappeared. Vaginal examination showed some retroversion of the uterus, but no marked displacement.

At the next menstrual period these symptoms returned with much greater severity than at any previous time. The temperature rose at times to 104° F., the pulse was almost imperceptible, and there was occasional delirium. The urine was diminished in amount, and contained traces of sugar. This attack was recovered from less perfectly than before, the liver remained slightly enlarged and the patient was quite weak. The following month the symptoms returned with increased severity, the temperature rose to 105° F., the pulse to 160, and the woman died. An examination of the blood, made at the beginning of this attack, showed 2,800,000 red blood-corpuscles to the cubic millimetre, the proportion of white to red cells being about as one to thirty.

To summarize briefly the above report: Five successive menstrual periods were replaced by five attacks of hepatic enlargement with acute inflammatory symptoms. From the first of these attacks the recovery was complete; from the fourth it was only partial; and the fifth attack proved fatal.

At the autopsy the liver was seen to be enlarged and adherent to the surrounding parts. Its surface was slightly roughened and dotted with yellow nodules and small red and black spots; its cut section presented much the same appearance. The spleen was enlarged and contained numbers of cheesy nodules. The left ovary contained a Graafian follicle filled with blood. Dr. Thacher, who made the microscopical examination, reported that the liver and spleen contained spots of congestion and hemorrhage, and also small areas of granular matter without visible structure, which were apparently necrotic. There were also numerous collections of abnormal cells, mostly of large spindle-cells with many giant-cells, which resembled sarcoma.

DR. GEORGE L. PEABODY said that the case looked to him very much like one of leucocythæmia.

THE PRESIDENT remarked that the proportion of white to red blood-corpuscles was not sufficiently altered to establish with certainty a diagnosis of leucocythæmia; it might be regarded rather as a leucocytosis.

DR. WILLIAM H. DRAPER then read the paper of the evening (see p. 393), entitled

### THE RELATION OF DIET TO URIC-ACID FORMATION.

DR. GEORGE L. PEABODY said that he could not help feeling that this question of uric acid and lithæmia was not so much one of chemistry as it was one relating to the vital processes of each individual person. It was within the experience of all that some persons, when confined to an exclusively nitrogenous diet, did not do well, and, on the other hand, a person who was getting along fairly on a moderate diet would suffer from an attack after taking a single glass of dry champagne. No one could suppose that the attack was the result of the mere chemical action of that one glass of wine. He asked Dr. Draper what sort of food he allowed his patients when he wished to avoid the carbohydrates.

Dr. Draper said that he had distinctly stated that it was not often necessary to withhold farinaceous or even saccharine foods entirely, but he believed that patients were relieved by diminishing the amount of this food taken. It is often necessary to remove only certain kinds of carbohydrates, such as fermented liquors, or fruits, or starchy matters. He had not intended to open up such a wide discussion, nor to go into the question of the treatment of gout. The point that he had intended to make was that uric-acid excretion is checked generally by withholding saccharine and amylaceous food. He believed that gout was very closely allied in some mysterious way to diabetes. Even when lithæmia exists alone, it is often as distinctly benefited by an anti-diabetic diet as is diabetes itself. Why this was so he could not tell; it might be due to some idiosyncrasy, to some peculiarity in a man's liver about which we know nothing at the present time. When he found it necessary to restrict the diet very greatly, he allowed spinach, salads, and the like, in addition to meat.

Dr. Peabody said that these green vegetables could not be looked upon as a food, for they were chiefly water, and the small amount that could be taken at a meal contained but very little nutrient material. They might serve to render the animal food more palatable, but that was all, and the diet was still purely an animal one. He did not see why fruits should be excluded, for their acids are converted into carbonates and thus render the urine alkaline.

Dr. Draper replied that the fruit acids were converted into bicarbonates, and these salts did not make the urine alkaline.

Dr. William M. Polk asked whether climate did not have something to do with this condition. He had never seen a negro on the Southern plantations with gout, yet they almost lived on sugar during a part of the year.

Dr. Draper thought that climate certainly did have something to do with it. The colored children got fat from their saccharine diet. Under other conditions the sugar taken might not make fat, but might instead give rise to lithæmia. It was not uncommon to observe people take on fat for a time, then this process would stop for some reason, and gouty symptoms would appear.

Dr. Sexton asked what effect corn-bread had in this condition. In those sections of the country where this entered largely into the diet it was his impression that gout was uncommon.

Dr. A. H. Smith said that his clinical experience was in accord with that of Dr. Draper, for he had often seen patients whose gouty symptoms disappeared upon the withdrawal of the carbohydrates. One patient, a boy, had an immense amount of urates in the urine whenever he took even a little piece of sugar. He believed that the three conditions of lithæmia, polysarcia, and diabetes were closely allied. It seemed to him hardly correct to say that green vegetables do not form tissue, for they certainly do in the lower animals. A horse will do a great deal of work when living on grass alone.

Dr. Peabody said that the herbivorous animals ate an immense amount of grass—they ate pounds and pounds—while a man eats only a few ounces. A man may eat a little two or three times a day, while cows eat all day long.

Dr. Kinnicutt said that horses can do a large amount of work on a comparatively small amount of fodder. They do not eat all day long.

Dr. C. L. Dana thought that Dr. Draper would find it very difficult to counteract the teachings of English physicians, which exerted a powerful influence on American practice. He could not recall a single English writer who did not exclude nitrogenous food from the diet in these cases. He had seen many persons, in the last few years, who were suffering from the nervous symptoms of lithæmia, and had systematically tried a non-nitrogenous diet. He had had some good results and some unsatisfactory ones, but had found usually that a nitrogenous diet would help those who were suffering from dyspeptic symptoms. Persons with the degenerative lesions of advancing life often do badly on a purely nitrogenous diet. He had found that the green vegetables agree very well with most people.

Dr. Polk asked whether no investigations had ever been made in these cases in regard to intestinal digestion and the action of ptomaïnes in producing lithæmic symptoms. Until such had been carefully made, the question could not be satisfactorily settled. In the treatment of this condition he had always paid much attention to the excretions, and this was the result of his observations as to the effect of climate upon the disease. It had always seemed to him that if we could create a Cuba for these patients it would do a great deal for them. Of course, he did not mean to assert that no one living in a tropical country ever had gouty symptoms, but he believed the disease in such cases was hereditary, and that it was seldom if ever acquired in hot climates.

Dr. Beverley Robinson said that he did not look upon diet in gout or lithæmia as the only essential point, and he did not believe that the retention of a certain amount of uric acid was essential to the production of the affection. It was necessary to watch the individual and to ascertain what he could digest and what not. There was a gentleman in this city, suffering from gout, whom he had watched very carefully. Last summer he went to Carlsbad for a course of the waters, and was there told that he was cured and that he would have no more gout. Some time ago, while walking up town, he became suddenly very short of breath. The attack passed away after resting at home, but recurred several times, and then the patient consulted the speaker. There was nothing in the man's urine or elsewhere to point toward gout, but finally, other things having failed to prevent the attacks of dyspnœa, he was put upon colchicum, and almost immediately uric acid appeared in large quantity in his urine. The speaker believed that gouty people did not drink enough water, and that if they would drink more they would suffer less from lithæmic symptoms. But they did usually eat too much, and it did not matter so much what kind of food was cut off as it did how much was taken. The diet should be regulated according to the individual indications, and should not be the same for the plethoric as for the pale, nervous sufferer.

Dr. A. A. Smith reported a case of

### DIFFUSE PHLEGMONOUS GASTRITIS.

The patient was a colored man, thirty-four years of age. He was admitted to Bellevue Hospital on February 26, 1889. The patient had suffered from no previous sickness of any kind, excepting measles and pertussis when quite young. Of late years he had been in excellent health; had never suffered from malarial poisoning, syphilitis, or rheumatism; had never sustained any severe injury; was not a hard drinker, and only occasionally drank more than two glasses of beer daily; had not been drinking at all for some time preceding his present sickness.

The patient on admission was perfectly conscious, but suffering intense pain in the abdomen, with marked tenderness on pressure, especially near the umbilicus. He said that when he arose the preceding day he did not feel so well as usual, though he complained of no definite symptoms beyond loss of appetite and feeling of indisposition to do work. Went to his place of business and fulfilled his duties as a cook. About two o'clock in the afternoon, after eating a light dinner, he was suddenly taken with cramp-like pains in abdomen, pain radiating chiefly from the umbilicus, and accompanied by vomiting of undigested food. Pains and vomiting, both of paroxysmal character, continued up to time of admission, viz., twenty-two hours from the beginning of the attack. He did not have any chill, nor experience any decided feeling of chilliness. When admitted the patient showed signs of great abdominal distress, vomiting at variable intervals a greenish-stained fluid, and utterly unable to retain anything taken into his stomach. The bowels were constipated, though

he had had one small movement the day before, unaccompanied by pain. Decubitus was dorsal, thighs flexed, abdomen only slightly, and not unevenly distended, tympanites not excessive, but most marked over the ascending colon. Cephalalgia was marked, and there was much dizziness. The urine was normal in quantity and quality, though the specific gravity was high.

February 27th.—Temperature still high; vomiting present; pain and tenderness more marked; bowels constipated; abdomen a little more distended and rather rigid; tympanites more marked; pulse more rapid, 120 to 130, feeble, fluttering; respirations, 25 to 35, and rather superficial. The patient lies with eyelids only partially closed, eyeballs upturned, just as when first admitted; easily aroused, and talks coherently.

February 28th.—Condition much worse. The temperature began to fall after 5 A.M., but the pulse became more rapid and feeble; not easily aroused. About 9 A.M. the man went into collapse, dying at 10.45 A.M.

February 29th.—*Autopsy* revealed diffuse, phlegmonous gastritis, almost the entire wall of the stomach being infiltrated with pus-cells, the mucous membrane itself being unaffected; no evidences of any ulcer or even break in its continuity. There was slight recent peritonitis overlying the affected part of stomach. The intestines and viscera were unaffected. No evidences of any form of inflammation elsewhere; endocardium unaffected.

This case presents several points of interest. The man gave a history of an illness beginning on rising, the day before admission to hospital. It will be observed he was admitted, February 26th. He was taken ill the day before, February 25th. He died, February 28th, at 10.45 A.M., about seventy-six hours after the very first symptom manifested itself.

The autopsy revealed a condition which is extremely rare, and one which is seldom diagnosed except in the autopsy-room. It would seem impossible to make an accurate diagnosis unless the patient lives sufficiently long to vomit pus. In this case a diagnosis was made of localized peritonitis, but what it was due to it was impossible to even conjecture. The peritonitis was probably secondary to the changes in the stomach-walls. There was no change in the intestine or liver, as is sometimes found in phlegmonous gastritis. There was no history of a blow over the epigastric region.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, September 23, 1889.*

ALEXANDER S. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

THE following nominations were made:

For *President*—Dr. A. S. Hunter and Dr. L. Bolton Bangs; *Vice-President*—Dr. J. Leonard Corning; *Secretary*—Dr. C. H. Avery; *Assistant Secretary*—Dr. W. E. Bullard; *Treasurer*—Dr. John S. Warren; *For Censors* (five to be elected)—Drs. Laurence Johnson, Daniel Lewis, G. H. Fox, N. G. McMaster, William M. McLaury, George E. Abbott; *For Delegates to the State Medical Society* (twenty-four to be elected)—Drs. J. O. Tansley, D. H. Goodwillie, William Stevens, A. S. Newcomb, F. B. Carpenter, Samuel Lloyd, P. A. Callan, Ralph Waldo, E. M. Liell, U. G. Hitchcock, W. A. Dayton, Charles A. Powers, Willy Meyer, H. D. Chapin, G. T. Elliot, John Dorning, S. D. Powell, R. T. Morris, Francis Valk, D. D. Jennings, W. C. Jarvis, L. L. Seaman, Malcolm McLean, E. H. Grandin, W. P. Northrup, R. C. M. Page, R. C. Shultz, R. B. Talbot.

DR. H. J. BOLDT read a paper entitled

### SOME ABNORMALITIES OF THE CONTENTS OF THE FEMALE PELVIS,

being some conclusions based on personal experience, with the diagnosis and treatment of various diseases of the female reproductive organs.

When the abnormality consisted of a tumor it had to be determined whether it was intra- or extra-peritoneal, to what part it belonged, whether the uterus, ovaries, tubes, etc.; whether solid, semisolid, or having fluid contents; its nature; whether likely to endanger life or disable the patient; what treatment, if any, was for the best interests of the patient. The author next considered the symptoms of ovarian cysts, which varied according to the size, position, nature, and complications. Bladder and bowel symptoms depended on the extent and density of the adhesions, the severity of inflammation in the tumor, and perimetritis. There was usually constipation and frequent micturition, yet he had seen the reverse in some cases of suppurating ovarian cysts in which the adhesions were exceedingly dense. He attributed the diarrhœa in such cases to a mild sepsis; although the temperature was never high, still, if taken a number of days at regular intervals, an occasional rise to 100° F. or above would be noticed. He had never seen a patient with pus intra-abdominal in whom records of the temperature for several days did not show fever. Speaking of the physical examination, he warned against the danger of rupturing the friable walls of the cyst by rude manipulation. He believed that one cause for suppuration might be found in the treatment which some patients received during months, and which, instead of allaying the localized peritonitis around the cyst, increased it, suppuration eventually taking place. Cases of small suppurating cysts located behind the uterus had invariably given the history of a previous course of painful local treatment. One of the most serious mistakes in diagnosis was to confound a retroflexed gravid uterus with this condition, a mistake which had frequently been made, and which was illustrated by one instance in his own practice.

A case was also related in which operation showed that what had been mistaken by the patient's former doctor for an ovarian cyst with rupture into Douglas' pouch was a pyo-salpinx and intra-peritoneal exudation, the tube having become displaced and the discharge of pus occurring periodically through the uterus. The efficacy of catharsis was most markedly manifest in this case. The second day after removal of the diseased tube and breaking up of adhesions of the other, the temperature rose to 105° F., the pulse to 140. Septicæmia was evident, and he had intended to reopen the abdomen and drain, but, remembering the unfavorable result of previous experience with this method, he decided to try catharsis. Although the patient had had two diarrhœal movements during the day, he gave her fifteen grains of calomel. The bowel began to move within about three hours, and by the following morning the temperature had fallen to 99° F., and the pulse to 110. The patient quite recovered.

An ovarian cyst surrounded by perimetric exudations and bound down firmly by adhesions to the uterus might be mistaken for a subperitoneal or interstitial fibroid of the uterus. A fibro-cystic tumor of the uterus of large size could hardly be diagnosticated. Malignant degeneration of abdominal tumors should be suspected if the growth had been present a long time and was causing emaciation. The adhesions in such cases could be demonstrated prior to opening the abdomen. As to the supposed uselessness of operating in cases of ovarian tumors which had already undergone malignant degeneration, Dr. Boldt coincided with the views of Freund, who had given the history of a number of apparently hopeless cases in which the operation had materially prolonged life and relieved distress. Dr. Boldt had had opportunity to operate in but one such case. The patient, he believed, was yet well.

The author had seen several cases like the following: A patient suffering for months or even years with localized pain in one ovarian region, which had never been markedly relieved by any form of treatment. A mass varying in size from that of a hen's egg to greater than that of one's fist was found on one side of the uterus, with hard, irregular outlines, almost immovable because of firm ad-

hesions, and in close contact with the uterus. Such of his cases had always proven on operation to be composed of firm perimetric exudate with a little pus in the centre, the tube and ovary matted together and inflamed. Most physicians treated them for cellulitis, and they had also been mistaken for malignant disease.

The most frequent error in diagnosis was to confound tubal disease with cellulitis and posterior displacement. But tubal disease of infectious origin invariably had a distinct history, being traceable to either the puerperal state, some uterine treatment undertaken for dysmenorrhœa or sterility, or to gonorrhœa.

Dr. H. T. Hanks opened the discussion. He said that although the paper covered a large field, yet twenty years ago half of the affections mentioned would have been grouped under one name, pelvic cellulitis or pelvic peritonitis. He had been particularly interested in the symptomatology of pelvic diseases, and dwelt on the importance of a thorough study of the subjective symptoms, which, followed by manipulation, would enable one to make the diagnosis in most cases before opening the abdomen. There was no question in his mind but what hæmatocele due to tubal pregnancy, pyo-salpinx due to gonorrhœal infection, and retroversion of the gravid uterus had each its separate symptoms, and it was the duty of the physician to ask questions and establish the exact diagnosis. He mentioned one case of papillomata of the right ovary in which removal had prolonged life, although subsequent operations had to be resorted to for renewed growth.

Dr. E. H. Grandin thought the most serious error in diagnosis was to mistake pregnancy for some other condition. Of recent years the truth had been impressed upon him that this error need never, or very rarely, occur. There were two signs of pregnancy of great value, yet they were often overlooked, the one becoming of value at the eighth week, the other at the third month. The first was Hegar's sign, and was based on the fact that in early pregnancy the uterus enlarged chiefly in the antero-posterior and transverse diameters, assuming the shape of a flattened sphere, and becoming boggy. The other sign was that pointed out by Braxton Hicks, being the rhythmical contraction of the uterus after the third month. It might have to be waited for five or even ten minutes. It had been said that fibrosities would give rise to this symptom, but he had never felt but one which did.

Regarding free catharsis, he was satisfied that it was one of the best means for enabling patients to withstand the septic condition. This was true not only of sepsis in pelvic diseases, but also in the puerperal state.

Dr. Kearney mentioned the fact that Hegar's sign was also present in extra-uterine pregnancy, and spoke of a case of typhlitis, with general peritonitis imminent, in which recovery followed catharsis by Epsom salt.

Dr. W. E. Forest said it was not necessary to abandon opium in puerperal peritonitis while adopting the treatment by catharsis; he gave one grain of extract of opium, ten grains of calomel, and ten grains of quinine in two capsules. Strange to say, catharsis was even more free than when calomel was given without opium.

---

Potassium Bromide and Belladonna for Enuresis.—Dr. J. T. Richards recommends very highly a combination of belladonna with bromide of potassium in the treatment of nocturnal incontinence of urine. He reports two cases in the *British Medical Journal*, of June 22, 1889, in which this mixture was effectual after belladonna alone and several other drugs had notably failed.

Pilsner Beer as a Diuretic.—Dr. Gruss, of Vienna, had a patient with heart trouble who was passing very small quantities of water. He told him to drink freely of Pilsner beer, and the quantity of urine passed rose almost at once from thirteen to fifty ounces a day. This remedy will doubtless become very popular.

## MEDICAL SOCIETY OF VIRGINIA.

*Twentieth Annual Session, held in Roanoke, Va., September 3, 4, and 5, 1889.*

(Special Report for The Medical Record.)

(Continued from p. 384.)

### Thursday, September 5th—Third Day.

Dr. R. S. Martin, of Stuart, read a report on

### Advances in Gynecology.

Massage (Brandt's method) is reported to be practised with great success by Dr. Boldt, of New York, in the following conditions: Chronic and subacute para- and perimetritis; all non-acute inflammatory uterine diseases; chronic and subacute öophoritis; catarrhal salpingitis; all uterine displacements, with or without adhesions, unless dilated tubes are present; rectocele and cystocele; uterine hemorrhages not dependent on neoplasms; incontinence of urine dependent on relaxation of the visceral sphincter; hematocele; floating kidney; and prolapsus recti. It is contra-indicated, according to some, in all acute inflammatory processes, dilated tubes, and in all conditions where suppuration is suspected. This treatment is not useful in patients with very fat abdominal walls. The séances vary from three minutes to a quarter of an hour.

Dr. Martin then exhibited an Outerbridge dilator—an ingenious instrument which acts also as a drainage-tube. In sterility dependent on stenosis this instrument is introduced, five or six days before menstruation, into the contracted cervix uteri and allowed to remain. It is also of value in sterility due to flexions. A full description of the instrument and its uses was given in The Medical Record of April 20, 1889. Electricity holds a high place in the treatment of carefully selected cases. Engelmann uses galvanism for inflammatory products which admit of restitution, indurations, deposits due to interstitial inflammation, certain neoplasms. Davis, of Birmingham, Ala., uses faradism for subinvolution of the uterus. It is useful in many cases of retroversion, many so-called pelvic inflammations, in amenorrhœa due to atrophy of the uterus, and in menorrhagia due to relaxation of the muscles. Many think electricity (after Apostoli's method) of value in the treatment of uterine fibroids; but the dangers of sepsis must be guarded against. Some think electrolysis of fibroids uncertain.

For carcinoma uteri Brown uses the curette freely, and applies on a tampon a saturated solution of zinc chloride. Mundé uses a weak solution of sesquichloride of iron. Schramm injects half to one grain in an ounce solution of corrosive sublimate into the diseased mass, two or three times a week, causing cessation of fetor and purulent discharges, and lessening the frequency of hemorrhages. The feeble absorptive power of the degenerated tissue offers immunity from mercurial poisoning. The following is an antiseptic and sedative suppository extensively used in Paris.

℞. Iodoformi ..... gr. xv.
Camphoræ ..... gr. iv.
Ext. belladonnæ ..... gr. j.
Ol. theobromæ ..... q. s.
M. Make one suppository. S.: Put high up in vagina at night.

High amputation of the cervix is advised if the disease has not passed beyond the internal os. If disease has not extended beyond the uterus, hysterectomy is advised. As to uterine fibroids, Coe scrapes away the hypertrophied mucosa. Vaginal hysterectomy has been done successfully. During 1888, abdominal hysterectomy was done 43 times, with only 9 deaths. Uterine anteversions and flexions are but rarely congenital, but results of previous parametritis. Use antisepticized laminaria tents to soften the tissue and render intra-uterine treatment more thorough. Use preliminary course of hot douches and

glycerine tampons, then straighten the uterus bimanually, and hold in place by pessary or intra uterine stem. Dilatation with bougies and the persistent use of hot water will usually effect a cure. Gooddell advocates thorough dilatation with steel-branched dilators when dysmenorrhœa is a prominent symptom. Wylie condemns pessaries, but dilates rapidly under thorough antisepsis. Alexander's operation for shortening the round ligament has grown in favor. Mundé reports 23 cases, with excellent results. Kellogg reports 65 successes out of 69 operations. Schucking has devised and practised successfully vaginal suture of the uterus in 18 cases for radical cure of retroflexed or prolapsed uterus. Hysterorrhaphy finds favor in Germany, where prejudice exists against Alexander's operation. A case of lacerated cervix, operated on by the reporter in May, 1886, was delivered of twins, each weighing eight pounds, in July, 1889, without further laceration. Herrick pares the lips and holds them in apposition, not by sutures, but by an elastic band shaped like the cervix, large enough to cover the whole os and cervix, with a small hole in the band to allow the secretions to pass. Dr. T. Gaillard Thomas does not claim that operations for diseases of women are especially liable to cause insanity, but he mentions six very significant cases in none of which were the kidneys at fault, nor could the sequel be charged to iodoform-poisoning.

Dr. Charles W. Pritchett, of Keeling, then read a

REPORT ON ADVANCE IN OBSTETRICS.

He first spoke of the vomiting of pregnancy. Hewitt analyzes fifty selected cases, and contends that these cases confirm his opinion that the vomiting is in almost all cases associated with, and dependent on, uterine displacement and thickening or induration of the cervix. Gill Wylie attributes it largely to induration of the cervix. Jaggard ascribes it to endometritis gravidarum. In the treatment of this complication Gunther, of Montreux, advises galvanism. Green reports cases cured by chloride of sodium. Collins and William Duncan report cases cured by the application of a ten per cent. solution of cocaine to the vagina and cervix. Rose recommends rectal injection of carbonic-acid gas.

*Anæsthetics.*—Recent writers accord antipyrine a very high place in the first stage of labor, relieving pain and fatigue, while the uterine contractions are not interfered with. Chloroform holds its own in the second stage of labor. Budin advises chloroform only to dull pain, and not to complete anæsthesia, unless to perform an operation more severe than the application of the forceps. Swieicki, of Posen, has used a mixture of nitrous oxide and oxygen in the proportion of four to one. Winckel regards the mixture as harmless, and especially useful in cases of elderly primiparæ.

*Antiseptics.*—The comparative results in hospitals in which antiseptics are used, and those in which they are not, are sufficient to show their great value in reducing the mortality of the lying-in chamber. Corrosive sublimate in weak solutions, and in careful hands, is still the queen of antiseptics and germicides.

*Eclampsia.*—There is yet a considerable want of unanimity as to the cause and treatment of puerperal convulsions. Santos believes that the albuminuria is the result of reflex irritation of the sympathetic and renal nerves, by the enlargement, and later on the contraction and retraction, of the uterus. Lusk says albuminuria is caused by renal insufficiency, and is not the cause of the convulsions. Pajot denies the dependence of eclampsia on albuminuria, but attributes it to a reflex cause.

*Mastitis.*—According to Richardson, this is the result of septic infection, and urges that the child's mouth be kept perfectly clean, and the nipple well washed with antiseptics. Monti advises that the fissures of the nipple be painted with a solution of gutta-percha in chloroform.

*Puerperal Septicæmia.*—It is disputed whether this disease is dependent on one or more organisms. Vidal claims that there are at least two, and that there is no characteristic difference between the germs of puerperal septicæmia and erysipelas. Gusserow denies their identity, and insists that erysipelas cannot cause puerperal septicæmia. Doyen says they are one and the same. Others assert that puerperal septicæmia is of an erysipelatous nature, and the fever typical of erysipelas.

Dr. A. S. Priddy, of Keysville, read the report on

ADVANCE IN DISEASES OF CHILDREN.

He had not found any material advance except in diseases of the alimentary canal. The researches of Holt, Escherich, and others with reference to intestinal bacteria were summarized, with the deduction that three factors must be kept in mind in studying the effects of micro organisms upon the human system: The nature of the organism; the dose, and numbers in which they enter; and the susceptibility of the patient. The two varieties of bacteria which have been isolated and studied in the intestines of young children, are the bacterium lactis ærogenes (found in the upper portion of the small intestine), and the bacterium coli commune. The first decomposes milk-sugar, with the development of lactic or acetic acid, to which the acidity of the intestine is due. After a full review of the subjects involved, the lessons are drawn that the infant must not be overfed, and that the milk (in bottle-fed cases) should be sterilized, and the vessels themselves that hold the milk should also be sterilized. Milk was first sterilized for food in Munich, in 1886. Dr. Caillé, of New York, introduced sterilized milk as an artificial food into this country in 1888, and the results have been favorably received. It remains sweet for six weeks, while boiled milk can be kept only four or five days, even on ice. Stomach-washing for gastro-intestinal disease, first used in Prague in 1880, was satisfactorily introduced by Seibert in New York, in 1888—especially serviceable in dyspeptic disorders attended with regurgitation of food, in cholera infantum, etc. Pass a long, soft, velvet-eyed rubber catheter, attached to a fountain syringe, through the pharynx into the stomach; pour in a cupful of warm water while the child is in the upright position; then tilt the child forward, and the water returns through the catheter. For intestinal irrigation, pass a Nélaton soft rubber catheter (with a hole in the end instead of at the side) some eight or ten inches into the bowel. Through this catheter, attached to a fountain syringe, pass a quart or two of warm water, containing a drachm of sodium salicylate to the pint of water. Though the treatment is not new, it is only during the past two years that it has become popular in this country—chiefly through the reports of Dr. Booker, of Dr. H. P. Wilson's Sanitarium, of Baltimore. It is useful in dysentery, gastro-enteric catarrh, acute and chronic follicular enteritis, etc. Dr. Priddy had used the treatment satisfactorily in a number of cases of gastro-enteric catarrh, dysentery, etc., relieving the nausea, vomiting, tenesmus, etc., and curing his patients.

Dr. George Tucker Harrison, of New York, read a paper entitled

FURTHER CONTRIBUTION TO THE STUDY OF THE ETIOLOGY AND PROPHYLAXIS OF PUERPERAL SEPTIC INFECTION.

The doctrine of auto-infection, which has recently been brought into great prominence, and the industrious researches of the bacteriologists, with the practical deductions from them, have divided obstetricians into two parties diametrically opposed to each other. The one side attaches all importance to the disinfection of the obstetrician (Mermann's subjective infection); the other regards it as a matter of necessity to subject the parturient woman, in a greater or less degree, to antiseptic measures (objective antisepsis). The writer took the ground of those who advocate the paramount importance of subjective antisepsis, in the paper read before this Society in 1885, and has had no reason to change his ground. Of course this position does not exclude the thorough cleansing and disinfection of the external genitals. The views of Kaltenbach were quoted, who insists upon it that an

obstetrician, even with clean hands, can induce infectious forms of disease. He believes that, as the surgeon disinfects his field of operation, so must the obstetrician disinfect the parturient canal, as well as the vicinity. Winter (*Zeitschrift f. Gyn.*, etc.), as the result of bacterial investigation, draws the inference that it is necessary to disinfect the cervix and vagina to avoid auto infection. Steffeck and Dolderlein arrive at the same conclusion. The writer believes that if the demands made by the bacteriologists should be generally acceded to, and it should become a universally accepted rule of practice that the cervix and vagina of every parturient woman should be subjected to thorough and energetic disinfection, an immense amount of injury would be inflicted. These disinfective procedures deprive the vagina of its physiological mucus, and render it more vulnerable. It becomes more liable to the attack of infective germs. Moreover, labor is mechanically retarded when the vagina lacks its normal mucus; nor must it be left out of mind that disinfection of the vagina and cervix is a painful manipulation. Probably the most serious objection which can be urged against the auto-infection doctrine is, that it diminishes the personal responsibility of the obstetrician, and that wholesome dread of infection disappears which everyone should have who examines a parturient woman. The distinction was made between septic infection and putrid intoxication. Cases of so-called auto-infection are really cases of ptomaïne intoxication. The micro-organisms of septic infection are streptococci. According to Bumm, the streptococci of erysipelas and phlegmonous inflammations are identical. Bumm's careful and exact bacteriological studies lend no countenance to the doctrine of auto-infection. Leopold's clinical experience is very striking. Of five hundred and ten women treated without vaginal douches, only nine had slight febrile phenomena. When the cervix and vagina were disinfected, there was a marked rise of morbidity. The doctrine of auto-infection is a retrograde movement, and tends to imperil our present attainments in the prophylaxis of septic infection.

Dr. I. S. Stone, of Lincoln, read a paper on

SOME GYNECOLOGICAL WORK OF THE PAST YEAR.

The paper was based upon experience of cases in the author's sanatorium where none but gynecological cases are received. A brief account was given of several cases of surgical interest, among others four cases of abdominal section. The author favors Emmet's operation for lacerated cervix, but thinks nearly all cases require the curette before resorting to trachelorrhaphy, and very much benefit may be derived from this procedure where the operation is not important. Tait's flap operation has given the most satisfactory results when required for lacerated perineum, and can be performed in a comparatively short time, thus simplifying a most tedious and difficult operation. Electricity came in for a brief notice only, but was not considered of definite value. The author claims exceedingly good results in neurasthenia attendant upon pelvic disease from the use of the Weir-Mitchell method of treatment.

Dr. John W. Scott, of Gordonsville, was the reporter on

ADVANCE IN PRACTICE OF MEDICINE.

After reviewing much of the germ theory as causative of a number of diseases, he concludes that we must look to local sanitary improvements rather than to quarantine alone for the prevention of epidemics—such as Asiatic cholera, yellow fever, etc. Gibier maintains that the bacillus of yellow fever closely resembles that of cholera. During the year ending May 1, 1889, Pasteur treated 1,673 persons bitten presumably by rabid dogs, and lost only three by hydrophobia after the conclusion of the treatment; six died during treatment, and four developed the disease a fortnight after leaving his institution. The microbe of typhoid fever is the bacillus of Eberth and Gaffky. It is of tenacious vitality, and may live for months in decomposing fecal matter, increasing in numbers at a temperature of 62.5° F. Drs. Kalb and Bartlett claim (*British Medical Journal*, January 5, 1889) what is next to an abortive treatment of typhoid fever by mercurial inunction. This treatment must be commenced before the ninth or tenth day. Cold baths are being again advocated. Ehrlich's diagnostic sign of enteric fever—reaction in the urine with one of the aniline derivatives—has been verified by Dr. Taylor (*Lancet*, May 4, 1889). Tuberculosis is a specific infectious disease, the constitutional manifestations of which are secondary to the bacilli, and due to toxic influences evolved during their increase of growth and number. The number of bacilli in the sputa bears no relation to the progress of the disease. The dry sputa is chiefly concerned in the propagation of the disease. The disease can be transmitted only through the medium of Koch's bacillus. It is not in the ordinary sense hereditary. The presence of the bacillus in the sputa is of positive value, but not of negative value in diagnosis. A rational prophylaxis is practicable, and we must still look more to prevention than to the cure of tuberculosis, as no non-injurious antiseptic has yet been brought forth successfully. The infectiousness of scarlet fever suddenly decreases about the sixth day and increases again about the twelfth, reaching its maximum by the sixteenth. The telluric origin of tetanus is gaining advocates. The disease may be produced by inoculation with earth which has recently been in contact with organic matter. The treatment of locomotor ataxia by suspension is approved, but with the injunction to be cautious in watching the effect on the patient during the operation of suspension itself. No case of Pott's paralysis ought to be regarded as desperate until after failure of suspension. Weil's disease is due to septic poisoning, and hence it is proposed to call it septic or infectious icterus. Dr. Scott's observations on the treatment of whooping-cough by inhalations of the oil of eucalyptus is beneficial in shortening the length and in ameliorating the severity of the paroxysms, and in prolonging the intervals between the spells. His method was to pour from one to two drachms of the oil on sponges and suspend several of them from convenient places in the room; at night, from the head of the bed so as to let the oil be constantly inhaled. A number of abuses of hygienic rules were mentioned, in the hope of getting practitioners to properly instruct their patients with regard to them, such as the common errors in our schools, the aversion of wives to becoming mothers, etc.

Dr. A. Jacobi, of New York, presented a communication on

ENTERALGIA AND CHRONIC PERITONITIS.

Enteralgia is always an irritation of a branch or branches of the sympathetic nerve. Its cause lies in the nerve or the intestinal tissues or its contents. Hysteria, hypochondria, malaria, gout, poisons, etc., may start the disease; or the pain may be reflected from spinal, liver, genito-urinary or skin disease—sudden chilling of the skin being a frequent cause. The pathological changes are congestion or inflammation, with their results. Acid food, certain drastics, hard scybalæ, fermenting foods, etc., are the common causes of enteralgia. The attacks are indefinite in length or suddenness. The temperature is rarely raised; the pulse is irregular; the skin becomes cold and clammy; sometimes dysuria, nausea, vomiting, constipation or diarrhœa occur. The tumidity of the abdomen changes its place under palpation, etc. Priapism and seminal discharges may occur with spastic rise of the testicles.

A common cause of enteralgia, often overlooked, is chronic peritonitis of secondary nature. New abdominal formations, peritoneal adhesions, swelled pelvic glands, etc., point to previous peritonitis. Floating kidney may start peritonitis, and thus become fixed in its dislocated position. Vertebral disease, psoas and iliac abscesses, hip-joint abscess, etc., may cause chronic peritonitis—oftentimes not recognized except post-mortem. Catarrhal "female diseases" are frequent causes, as are violent

cohabitation, the puerperal state, etc. Biliary calculi, perinephritis, splenic and pancreatic diseases, infantile intussusception, a preceding attack of peritonitis, etc., are also causes. Simple intestinal catarrh grows speedily into enteritis. Peritonitis is likewise communicated to the muscular and mucous tissues—and thus extends the œdematous infiltration, paralysis, and hence constipation. Thus also diarrhœa, intestinal ulceration without perforation, etc., may cause local peritonitis. Diagnosis of chronic peritonitis is not always easy. Respiration need not be accelerated in pelvic peritonitis, perimetritis, and pericystitis. Vomiting is sometimes wanting; diarrhœa is not infrequent, but constipation is the rule; the abdomen may be tumid, and the horizontal position is often uncomfortable. The seat of inflammation or adhesion may sometimes be told by placing the patient on his back; extend and then flex the extremities, and then use pressure—soft, hard, sudden, and gradual. Often, however, it is best to make deep pressure; if no pain, relieve the pressure suddenly when localized pain may be felt. Change of position of the bowels may arouse pain; sharp pain after full meal may point to adhesions of the stomach; if pain occur three or four hours after eating, look for chronic colitis; if after quickened inspiration, then perihepatitis, etc. Variability of pain depends on degree of irritation or congestion. Extensive pelvic peritonitis may not give pain except when waked up by defecation, cohabitation, micturition, etc. In pericystitis, when urine is about half voided, and the bladder begins to contract more efficiently, a localized pain above the pubes, increased by pressure, develops, much resembling the spasmodic pain of vesical catarrh. Flatulence, etc., develops enteralgia in chronic peritonitis; stenosis of the bowel, twisting, adhesions, etc., result, thus interfering with the intestinal functions. In short, the sequelæ of chronic peritonitis are very various. The indications of treatment of the enteralgia of chronic peritonitis are determined by its results and symptoms, such as intestinal sluggishness, adhesions, etc. Subacute and acute peritonitis require absolute rest, support for the knees, ice or hot applications according to circumstances, opiates, etc. Some are now recommending large doses of magnesia sulphate and turpentine enemata; but a treatment under which an occasional patient may escape death must not supersede one which has proven to be successful in most cases, and beneficial in all. Localized attacks, mainly in the right hypochondrium, demand local applications; a few leeches occasionally and morphia subcutaneously may be required. Old adhesions, etc., are not amenable to medicines. Great physical exertion, pressure on abdomen, etc., must be avoided. Keep bowels regular. Wear a snug bandage over the whole abdomen for years after the last complaint of pain. Generally this bandage, held down by a perineal band, gives immediate relief. Without the immobility given by it to the sore intestine he does not expect a case of chronic peritonitis to do well.

Dr. W. D. DeGarmo, of New York, read a paper on the

SURGICAL TREATMENT OF HERNIA.

Dr. John Ridlon, of New York, read a paper on

SOME PRACTICAL POINTS IN THE TREATMENT OF HIP DISEASE, WITH SPECIAL REFERENCE TO THE USE OF THOMAS' SPLINT.

The paper was addressed to the general practitioner, and the means at his hands for the treatment of hip disease were chiefly considered. The difficulties in the way of obtaining and using the various traction splints were shown. Plaster of Paris was considered as a convenient and comfortable form of dressing, but one not easy to apply properly. Traction by weight and pulley in bed was not approved of, while Howard Marsh's method was approved of for those cases where traction is indicated, and rest in bed not contra-indicated. To one who was satisfied to treat tubercular joint disease in any part of its course without traction, or who is so circumstanced, as the general practitioner is, that he must treat all walking cases without traction, and to one who believes that immobilization, and not traction, is chiefly indicated in the management of these cases, Thomas' splint would prove of great service. It can be made by a blacksmith or harness-maker at a cost of not more than $2.50. Splints, pattens, and wrenches were shown and their construction and application described. The writer believed that Thomas' splint should be applied at once, and that we should not wait to reduce the deformity by other means, and that the patient should be kept in the horizontal position, but not necessarily in bed, until the muscular spasm had in a great measure subsided.

Dr. Joseph A. White, of Richmond, read the report on

ADVANCES IN OPHTHALMOLOGY, RHINOLOGY, OTOLOGY, AND LARYNGOLOGY,

which was rather a critical review of the more important literature of the past year interwoven with some of the practical results of his own large experience in this special line of practice, particularly in reference to operations on the ocular muscles in the line suggested by Landolt, Abadie, and Stevens, of New York. His results with modified tenotomies and resections of the recti muscles in cases of headache, eyeache, neuralgia, confirm those of Stevens, while he is not prepared to speak of their value in cases of epilepsy, mental defects, etc. This method of operating he has also substituted in his practice for the old-time squint operation and he gets more accurate results than formerly. He also emphasized the dependency of ear diseases upon nasal troubles, and the fact that nasal catarrh was to be cured only by surgical procedures.

Dr. J. Herbert Claiborne, Jr., of New York, read a paper entitled

PRIMARY IRITIS; ITS DIAGNOSIS AND TREATMENT.

It opened with an anatomical description of the iris and contiguous parts. It was important to remember that in a condition of health the edge of the pupil rested on the anterior surface of the lids in moderate dilatation. The diagnosis was to be made by the signs rather than the symptoms of the disease. Pericorneal redness, steamy cornea, clouded aqueous, discolored iris, small pupil, irregular and puckered edges of pupil, tenderness on pressure in the ciliary region, were the symptoms indicating a high condition of ciliary congestion, but not necessarily of cyclitis. Treatment was comprised under the great "therapeutic trilogy," local depletion, irritation of pupil, systematic treatment. Local depletion was best obtained by that leech that takes deepest hold, sucks longest, and draws most blood. Bleeding should be encouraged by hot applications to the bites.

The position for the leeches was in the temporal fossa in a horizontal line with the outer canthus of the eye, to drain the temporo-malar branches of the lachrymal arteries. Dr. Claiborne preferred to combine cocaine with mydriatics on account of the greater mydriatic power of such combination and the analgesic effect of cocaine. He preferred Duboisine (ten per cent.) combined with cocaine (six per cent.). In regard to systemic medication, use blue ointment, salicylate of soda, and iodide of potassium, the iodide combined with bichloride or biniodide of mercury, antipyrine, and Russian or Turkish baths, and quinine for its general tonic effect. He wished to lay much stress on the value of salicylate of soda, particularly in rheumatic iritis; it was also of great value in the specific form, as assisting the action of the other agents. There is no need of opium or morphine in iritis; if the pupil could be dilated pain would cease; if it could not, antipyrine was a good substitute for morphine. Too much stress could not be laid on the importance of the early treatment of iritis with regard to preserving the sight. The responsibility rests with him who sees the case first.

Dr. Lewis G. Pedigo, of Roanoke, read a report on

ADVANCES IN NEUROLOGY AND PSYCHOLOGY.

He regarded the development of the suspension treatment of locomotor ataxia as the most important step of progress in neurology in the past twelve months and devoted considerable time to the consideration of this subject. Other items of progress in neurology were reviewed; the problems of asylum management and general care and treatment of the insane received due attention. A brief allusion was made to Stephen Smith's project of a law for commitment and detention of the insane. The present status of various questions of medical jurisprudence was presented at length.

The latter portion of the paper was devoted to hypnotism and allied phenomena. This portion of the paper was illustrated by actual experiments before the society on a subject who, the doctor claims, is one of the very best and, in some respects, most remarkable hypnotic subjects in the world. He succeeded by his own modification of the Bernheim and Charcot methods in throwing this subject into the hypnotic trance in about one-third the time required by Bernheim to hypnotize his very best subjects. La petite hypnose and la grand hypnose (in its three stages), as delineated by Charcot in Salpêtrière, were demonstrated in clear and rapid succession.

Dr. E. M. Magruder, of Charlottesville, reported two cases of

NEURECTOMY FOR FACIAL NEURALGIA, WITH RECOVERY.

His first case was a gentleman, seventy-one years of age, who had had persistent neuralgia for fourteen years, that no medicine cured, although he had consulted eminent specialists. Seven drops of fluid extract of gelsemium, every three hours, gave greater relief than any other medicine except morphia. But all medicines failing, the patient was chloroformed, and, with strict antisepsis, an incision was begun just below the lower orbital margin, over the infra-orbital foramen, straight downward, parallel with the nose, toward the lip, and ended on a level with the lower border of the ala nasi—about an inch incision. The fascia and fibres of the levator labii superioris were torn through with the handle of the scalpel, and the nerve exposed at its exit, where it divided into two branches. Each branch—the palpebral, the nasal, and the labial—spreading into a fan-shape as it neared its destination, was dissected out as far as it could be followed without mutilating the face too much. The main trunk was then seized with forceps at the foramen, drawn out as far as possible without breaking it, and cut off close to the bone, after which the various branches were divided at their farthest point of dissection. The wound was closed with fine silk sutures. There was at first considerable paralysis of the side of the face, and loss of sensation, but these disappeared, except from the right half of the upper lip, which is still without motion or sensation. There has been no recurrence of the neuralgia. The patient feels like a new man.

Case II. was a lady, fifty-eight years of age, who has had facial neuralgia for ten years. At first it was confined to the left lower jaw, never passing the middle line of the chin; but afterward extended to the left external ear, temple, and side of head above and behind the ear (auriculo-temporal), to the left side of the tongue (gustatory), and then to the left side of the floor of the mouth (mylo-hyoid). The diagnosis was neuralgia of the inferior dental nerve, with reflex and sympathetic phenomena exhibited by the auriculo-temporal, gustatory, and mylo-hyoid nerves. As to treatment, teeth had been extracted, analgesics had been used, etc., and, finally, total neurectomy of the inferior dental nerve—including its branches—was done, with cure. In the operation, avoid injury of the facial artery and Steno's duct. Entering the scalpel just in front of the posterior border of the ramus, just below the parotid duct and lobe of the ear, a curvilinear incision was made downward, half an inch in front of the inferior maxillary angle, then forward a little above the lower border of the ramus, and upward just behind, and avoiding the facial artery, stopping short of the line of Steno's duct above. The flap thus shaped was raised by shaving the masseter muscle from its attachment to the outer surface of the ramus, and the bone laid bare. With a half-inch trephine cut out a button of bone from the centre of the outer plate of the ramus, exposing the nerve in its bony canal. Seizing the proximal end of the nerve with forceps, strong traction was made from the direction of its origin; it was then cut off with scissors, close to the bone, as it entered the circular cavity made by the trephine. Then, the wound being stuffed with moist antiseptic cotton, and the hemorrhage stopped with pressure, a second incision was made, an inch long, horizontal in direction, over the mental foramen (below the root of the second lower bicuspid tooth), beneath the depressor anguli oris, disclosing the mental nerve and its branches beneath the last-named muscle. The nerve was grasped with forceps and pulled upon, but broke off at its point of exit. The branches were then dissected out and cut off as far as possible from the foramen. Then returning to the first wound over the ramus, and chiselling away the wall of the dental canal, or one-eighth inch from the circular cavity in the ramus, so as to expose this end of the nerve which had been divided by the distal side of the trephine, it was drawn out of the dental canal with forceps, in its entire length from the ramus to the foramen. In all, three and three-eighths inches of nerve-structure were removed. The wounds were closed, and the patient was perfectly relieved, without any return of neuralgia since. The paralysis of the left side of the face disappeared in about two weeks.

The lesson learned is, in all operations for facial neuralgia remove as much of the troublesome nerve and its branches as the anatomical formation of the parts will possibly allow without rendering the procedure too grave.

Dr. C. R. Cullen, of Waldo, Fla., read a paper on

RAILROAD INJURIES.

He reported eight parties injured by railroad accidents—several had ribs fractured; two had hands crushed; one besides broken ribs, had cystitis, fractured arm, and abscesses; one had fractured femur, which was finally removed, and the foot on the other leg badly crushed. Several bones and pieces of bone were successfully removed, with full restoration to health. Dr. Cullen urged that doctors not engaged in the service of railroads insist upon the same compensation, when they are called upon for such service, that is received by doctors engaged in railroad service.

Mr. Hugh Blair, of Richmond, read, by invitation, a paper on

DIAGNOSIS BY MEANS OF URINARY ANALYSIS.

Harley says the state of the urine is a key to the condition of the body. While some diseases may not affect the urine, morbid urine indicates disease. Renal inadequacy (notable absence of urea and other solids), due to want of the necessary nerve-influence, is shown by the low specific gravity of the urine, other causes being excluded. In overworked nervous systems, excess of alkaline phosphates in the urine occurs. Probably the nervous system is fed with phosphorus by licithin. The best way of supplying phosphorus to licithin is to give hypophosphites. If indigestion and improper metabolism occurs, deleterious matters accumulate in the blood; if of nitrogenous character, the kidneys excrete them if they are eble. Destructive metamorphosis of albuminoids in the liver forms urea. Uric-acid crystals—easily recognized by the microscope—appear in the urine in some functional hepatic disorders and lesions, causing gout, chronic nephritis, renal calculi, etc. If the crystals do not appear, excess of urates, acid urine, with high specific gravity, are present. Lithæmia (uric acid in the blood) is a chronic condition of the overworked and over-anxious, is

not so serious as gout, but is ever active in causing obscure and distressing symptoms. It points to chronic functional disturbance of the portal circulation, and is recognized by the high specific gravity of the urine, its acidity, excess of lithates and phosphates, and, often, oxalate of lime crystals, and especially pigments in the urine. It gives a peculiar change in color in the urine during Pavy's copper test for sugar. Diabetes indicates grave systemic disease; but it should be differentiated from hydruria and polyuria. Icteric urine stains white cloth yellow; but its diagnostic value is not of practical use. In short, the value of urinalysis extends to every disease characterized by pathological urine, as the Bright's diseases, pyelitis, cystitis, etc. Numerous urinalyses made by him for physicians had enabled practitioners to determine their diagnosis, and oftentimes save the lives of patients.

Dr. A. F. Kerr, of Williamsville, reported a case of

EXTERNAL GLANDERS, OR FARCY, IN MAN.

The rarity of the disease, especially in mountainous regions, justified, he thought, a note or two about the case. Glanders is an infectious disease, principally of domesticated equine animals, and communicated to other animals and to man by inoculation of the glanders bacillus. It originates in solipeds, although it has been known to originate in cloven-footed animals. Having originated, infection occurs only for a short distance through the atmosphere, or the disease may be communicated through the ingestion of infected matter, or through the seminal secretions to the female in coitus, etc. In man, the chief source of infection is the horse—being rarely communicated from man to man. The point of attack is usually an abrasion upon the skin or mucous membrane. The incubative period is from one to four days in inoculated cases. The wound becomes tense, swollen, painful, with a dark or yellowish erysipelatous redness, and the edges become puffy and everted. A sanious matter issues, and the surrounding lymphatics become swollen and red, and the glands become enlarged and tender. Constitutional disorder sets in in a few days—languor, extreme weakness, and prostration, with aching in the limbs and head, rigors alternating with fever, or a continued fever after the first violent chill; sometimes there is nausea and vomiting, and even diarrhœa. When not due to external inoculation the febrile symptoms appear first, and then the other conditions which have been noted first in the description of cases due to external inoculation. The phlegmonous swellings along the lymphatics become abscesses, and discharge small quantities of a thick slimy pus. The resulting sores become ulcerous, with grayish base. Temperature rises perhaps to 104° F.

His case was a young healthy man, in 1886. He contracted glanders from treating a mare supposed to have "greased heel," or "scratches." He first noticed a painful swelling on the point of the second finger of the left hand, which had been slightly cut with a penknife. The swelling was yellowish, edges of wound everted and puffy, and discharged a thin, sanious material; the surrounding lymphatics became enlarged, and all the fulness of the history of glanders in man was complete. Treatment began with a brisk purge, followed by quinia and muriated tincture of iron, and an exclusive milk diet. The swellings on the forearm were freely laid open and cauterized with nitrate of silver, all diseased tissues removed, and the resulting sores packed with iodoform, over which was laid medicated jute. Subsequent washings were made with carbolized water. Recovery was prompt.

Dr. W. W. Parker, of Richmond, presented a paper on

A FEW ORIGINAL OBSERVATIONS ON BLOOD GRAVITATION IN HEALTH AND DISEASE,

of which the following were the conclusions:

1st. The first wound ever inflicted upon the human body was probably upon one of the extremities, and the relief following the elevation of the wounded member was the first illustration of blood gravitation in disease.

2d. A case reported of the wonderful curative power of elevation—the leg 80°—of a boy struck in the tibia by a base-ball.

3d. A singular case of death from the application of a mustard-plaster to the ankle, being an exception to the rule, yet establishing it.

4th. The gravitation of blood in the stomach made useful in preventing emesis in certain cases.

5th. A remarkable case of acute inflammation of the neck of the bladder, in a woman, with retention of urine, at once removed by the forcible elevation of the hips of the patient. Other cases reported.

6th. The avoidance of varicose veins of the legs in shopkeeping men and women by sleeping on a double inclined plane, and the importance of those predisposed to apoplexy sleeping with the head well elevated.

7th. The effect of the position of the body in phthisis, in liver, and other congestions. A case of an infant, with suffocating catarrh, at once relieved by the elevation of the head and chest.

8th. A beautiful illustration, found especially in the herbivorous or grazing animal, of nature's plan of counteracting the hurtful gravitation of blood to the brain.

9th. A lesson suggested from these considerations and facts to those unwise doctors and deluded people who think "a man cannot die till his time comes." That mechanical law in the body is as inflexible as the same law in the machine, and loss and ultimate destruction will come as certainly, from the neglect of these laws, to the one as to the other.

Dr. A. C. Palmer, of Norfolk, presented a paper on

OUTLINE TESTS FOR MUSCULAR INSUFFICIENCIES OF THE EYE.

Leaving out of consideration cases of strabismus and the like, he devoted attention to the more minute forms of insufficiencies known by the term heterophoria. In strabismus one eye soon accustoms itself to see the object looked at, while the other is idle, as to effort at vision. But in heterophoria there is acute normal vision, in which every detail of an object is seen; but the external rectus of one or both eyes is too weak to prevent the internus muscle from turning the ball in, just past the normal axis. Eyes such as these have to swing a very little way to make the image seen with one eye a little to one side of that seen with the other; and the confusion resulting is all the worse from the very fact that each eye sees so clearly that neither image can be ignored. The patient has before him two similar images, which are continually receding from, and blending with, one another. But he will involuntarily overcome this blurring of outlines, if he can possibly spur up the externus muscle to pull the eye out to its proper place. Just these insufficiencies, or strains, produce more mischief than true strabismus.

Heterophoria is subdivided into esophoria (eyes tend to turn in too far), exophoria (tend to turn out too far), and hyperphoria (where one eye swings on a higher level than its fellow). Prisms deflect an image toward their apices or their edges. The relative strength of each of the four recti muscles, in their normal condition, is presumed to be ascertained. Thus the externi should diverge the eyes sufficiently to make the image single when prisms of 8° are placed before them, with their bases in. The interni, after a little trying, should converge sufficiently to single images when prisms of 50° are placed before them, bases out. If a patient with neurasthenia presents, place him in an erect position, and direct his vision on a lighted candle twenty feet off. Then cover each eye alternately, and notice whether the light moves up or down, or to the right or left. This parallax test, introduced by Dr. Alexander Duane, of New York, often establishes at once the form of insufficiency. But should it not do so, then use the prism tests, which the paper described in de-

tail. Dr. Palmer then explained the application of glasses to overcome each of the insufficiencies.

Dr. Henry V. Gray, of Roanoke, read a paper on

THE THERAPEUTIC POSITION IN SEXUAL CONGRESS.

Many husbands will not keep their promise of continence even when the wound is inflamed. What is to be done? Advise the husband that if he will have intercourse, to do so with the wife in the position for introducing Sims' speculum. For in this position the womb rises up beyond the reach of the largest penile organ. The perineum gradually relaxes in the effort, and the womb does not receive a bruise or a jar. He has in several instances advised this mode of sexual intercourse, greatly to the relief of his patients with womb and ovarian diseases.

Dr. D. Mayer, of Charleston, W. Va., delegate from the Medical Society of West Virginia, read a paper on the

USE AND ABUSE OF OBSTETRIC FORCEPS.

He showed that when the forceps are properly used they are not damaging; that harm may come when used too late; that the time has arrived in obstetric advances when the practitioner will be compelled to use them because intelligent women demand their application to shorten their period of suffering.

Dr. L. B. Anderson, of Norfolk, Va., presented the

REPORT ON HYGIENE AND PUBLIC HEALTH,

in which he classed etiological factors into 1, those which are known; 2, those which are purely hypothetical and chimerical, such as malaria, vegetable parasites, bacteria, etc.; 3, those that are partly demonstrable and partly hypothetical, namely, ptomaïnes and leucomaïnes—from which sanitary laws are deduced.

Dr. J. G. Wiltshire, of Baltimore, Md., read a paper on

ANÆSTHETICS,

but retained his manuscript for some revisions, etc., before presenting it to the Committee on Publications.

After the session had been adjourned the members and guests met to enjoy a magnificent banquet, given by the profession and citizens of Roanoke.

## AMERICAN PÆDIATRIC SOCIETY.[1]

*First Annual Meeting, held at the Army Museum Building, Washington, D. C., September 20 and 21, 1889.*

First Day, Friday, September 20th—Morning Session.

The Society was called to order by the President, Dr. A. Jacobi, of New York.

ADDRESS BY THE PRESIDENT.

He briefly outlined the history of pædiatrics, its relations to other branches of scientific medicine, and its claims to be considered a speciality, viewing it in the light of internal medicine, surgery, neurology, physiology, psychology, embryology, and public hygiene. The following extract from this address will enable the reader to gain some idea of its scope and great value. "The most vital questions of public hygiene are most intimately connected with pædiatrics. It is mainly two subjects that attract the attention of those who take an interest in children. I allude to the school and to constitutional diseases. My remarks to-day can be but fragmentary, but still I must not, both in the interest of our science and human society, omit to emphasize the fact that it still appears that our schools were establishments organized to produce near-sightedness, scoliosis, anæmia, and both physical and intellectual exhaustion. Contrary to the treatment a colt receives at the hands of its owner, human society or the State permits or directs that the powers of a child should be rendered unfit for its future functions, physical, mental, and moral, for these three are indelibly interwoven. It requires physical and mental education to fertilize the soil for the evolution of morals. Thus the physician, and especially he who makes pædiatrics his special study, is a pedagogue by profession. The question of school-house building and school-room furniture, the structure of bench and table, the paper and the type in the books, the number of school hours for the average child and the individual pupil, the number and length of recesses, the hours and duration of intervening meals, the alternation of mental and physical training, the age at which the average and the individual child should be first sent, have been too long decided by school boards consisting of coal merchants, carpenters, cheap printers, and under-taught and over-aged school mistresses; not, however, of physicians. The health and vigor of the American child in early years seem, according to Bowditch, superior to those of the European; why is the youth and maiden, particularly the latter, so inferior? Why is it that anæmia and neuroses eat the marrow of the land, and undermine the future of the country by degenerating both the workers and the thinkers of the community, and the future mothers? If there is a country in the world with a great destiny and a grave responsibility, it is ours. Its self-assumed destiny is to raise humanitarian and social development to a higher plane by amalgamating, humanizing, and civilizing the scum of all the inferior races and nationalities which are congregating under the folds of our flag. Unless the education and the care of the young is carried on according to the principles of a sound and scientific physical and mental hygiene, neither the aim of our political institutions will ever be reached, nor the United States fulfil its true manifest destiny. That destiny is not so much the political one of excluding Europeans from our continent, North or South—for indeed the participation of European civilization in the gradual work of removing barbarism ought to be very welcome—but of raising the standard of physical and mental health to possible perfection, and thereby contributing to the welfare and happiness of the people."

Dr. Francis Huber, of New York, reported

TWO CASES OF DOUBLE EMPYEMA.

The writer gave the details and the results of his cases, and presented a very complete list of all the cases of double empyema which he could find in the literature of the subject.

Dr. Charles Warrington Earle, of Chicago, read a paper entitled

SUBCUTANEOUS EMPHYSEMA IN CHILDREN.

He gave the details of a very interesting case which followed a catarrhal pneumonia, and resulted in death. The subcutaneous tissues of the forehead, cheek, neck, and of the entire trunk, anteriorly to Poupart's ligament, and posteriorly to the iliac crest, were filled with air. It appeared in the neck first, and rapidly extended to the other parts. No autopsy could be obtained. He gave the histories of many cases, and discussed the causes of this condition and its treatment. He said that, as a local affection, it was found after operations and injuries in the vicinity of, or involving, the respiratory tract; or by the introduction of air through a tube in the loose subcutaneous tissue. General emphysema was rare in children, and was caused by interference with, or obstruction to, the respiration. Prognosis was good, unless the preceding disease had brought about great depression.

Dr. A. Caillé, of New York, reported a case of

MEMBRANOUS CROUP (LARYNGO-TRACHEITIS) IN A GIRL OF TWELVE YEARS OF AGE—TRACHEOTOMY—RECOVERY.

There were no visible signs of membrane in the nose or pharynx. Digital examination of the larynx revealed a stiff and thick epiglottis, and a marked flattening of the funnel-shaped laryngeal entrance. The treatment before operation consisted of small doses of bichloride of mercury in a watery solution with wine of ipecac. There was

[1] Organized in Washington, D. C., September 18, 1888.

a piece of pseudo-membrane coughed up nine hours before the operation, after which there was temporary relief to the dyspnœa.

Auscultation showed little respiratory murmur in the left lung, and during inspiration a short "flap" sound could be heard, which was thought to be due to detached membrane. After the operation, the temperature rose to 102°, 103°, 104° F., and this febrile condition persisted for one week. During this time a large amount of membrane was removed through the tracheal opening. (A bottle containing this membrane was exhibited.) A continuous spray, salt-water being the most acceptable, was absolutely necessary to insure comfortable breathing. The tube was removed on the fourteenth day, and the child made a good recovery.

Dr. Caillé also read a paper on

PERSONAL PROPHYLAXIS IN DIPHTHERIA.

He said that the acceptance of the principles governing antiseptic wound treatment has given a new stimulus to the study of disease prophylaxis. At the present stage of our knowledge, specifics for diphtheria are an illusion, and the medical profession should admit to the public that the treatment is entirely symptomatic. From a study of the subject, Caillé has come to the conclusion that municipal control of diphtheria is inadequate and impossible, just as the municipal control of infectious wound disease would be impossible. A good surgeon will find it possible to secure aseptic wound healing in filthy and infected localities, by directing his efforts to the parts liable to be infected. The physician's efforts to prevent and check diphtheria must lie in the same direction, though tempered with the full understanding that methods of occlusion such as in antiseptic surgical dressings are not applicable to the usual sites of diphtheria. It is positively known that diphtheria is infectious—is due to germs—and is first a local deposit, and a hyperæmic or defective mucous membrane favors its localization. The germs looked upon by many authorities as pathogenic, have been found in the naso-pharynx, buccal cavity, in carious teeth, etc., of persons in ordinary good health, who may harbor them for a time without becoming infected. When, however, a favorable condition of the mucous membrane is present infection takes place. In order to prevent diphtheria, therefore, we must seek to carry away putrid matter and keep in a healthy condition such parts as are liable to become diseased. That this can be done by nasal insufflations and gargling of non-irritating antiseptic liquids, and by reducing large tonsils, and filling or removing bad teeth, had been shown in a previous report by the writer. He has instructed many families in the employment of personal preventive measures during the past five years, and is firmly convinced of their value and easy application. He uses salt, alum, boric acid, potassium permanganate, potassium chlorate, and Labarraque's solution in water, which is dropped lukewarm into the nose, and is used as a gargle by older children and adults, two or three times a day. The same measures are adopted to prevent secondary diphtheria in every case of scarlet fever, measles, whooping-cough, etc. The author cited a number of cases, and gave instances in which the views expressed in his previous communication were corroborated. He suggested to his colleagues that a trial of this method would convince them of the great value of personal prophylaxis in diphtheria.

Dr. C. W. Earle, of Chicago, read a paper entitled

THE NECESSITY OF PROLONGED REST AFTER SOME ATTACKS OF DIPHTHERIA.

He said that he desired to call special attention to this class of cases, and to obtain the endorsement and influence of this Society, so that we can go before the great general profession and convince them that these cases require special care and prolonged rest in bed. He often keeps them in bed two or three weeks after all symptoms have subsided. This may not be necessary in every case, but it is safer. It is absolutely demanded, however, in all cases in which symptoms of paralysis are present, and should be insisted upon until every sign denoting it has disappeared. He urged that in the treatment of these cases the point of most importance, and most to be insisted upon, was prolonged rest in the recumbent position.

---

AFTERNOON SESSION.

Dr. J. H. Fruitnight, of New York, read a paper entitled

THE TREATMENT OF SCARLET FEVER AND ITS COMPLICATIONS.

In the treatment of the febrile condition, he obtained the best results from the administration of the tincture of aconite root in doses of one drop every two hours. His experience with antipyrine and antifebrine had not been such as to lead him to continue their use; and, although he had had no experience with the hydropathic treatment, he would hesitate to employ it except in desperate cases.

In milder cases, he treated the angina and pharyngeal symptoms with tincture of chloride of iron. In those cases in which a deposit had formed, he added the hyposulphite of soda, and in very severe cases the bichloride of mercury. When the exudate was extensive, he used trypsin in spray, alternating with a weak preparation of Lugol's solution or carbolic acid. The adeno-cellulitis, which is not uncommon, he treated with absolute rest, all manipulation of the parts being positively forbidden. If suppuration occurs, it is encouraged, and as soon as pus can be detected it was evacuated.

He treated the nephritis by rest in bed, warmth, and a generous milk diet. Hot vapor bath and digitalis were given when there was much dropsical effusion. There tincture of chloride of iron was not withheld, and when needed hydragogue cathartics were given, and for their diaphoretic effect the muriate of pilocarpine and jaborandi were used. He treated the otitis by warm fomentations to which an anodyne was added. After suppuration was established, he used antiseptic injections followed later by astringent ones, and for the pain he dropped into the ear a weak, warm salt solution. When the inflammation was severe, he applied leeches to the tragus, and when the mastoid cells threatened to be involved, leeches were also employed. The rheumatism complicating scarlet fever was treated the same as a simple rheumatic attack, *i.e.*, with the salicylate or salol and alkalies. Other complications were treated *pro re nata*.

A general principle of treatment was to keep up the strength of the patient, hence cardiac stimulants were employed early in the course of the disease, combined with good, nutritious, and easily digested food. The sick-room should be cool and well ventilated, and the isolation of the patient should be insisted upon as a prophylactic measure. Inunction of the skin was not advised, as it is thought to interfere with desquamation, but instead the writer recommended warm baths impregnated with an antiseptic solution.

Dr. Joseph O'Dwyer, of New York, read a paper entitled

THE APPARENT PHYSICAL CONTRADICTION INVOLVED IN THE REINFLATION OF A COLLAPSED LUNG WHILE AN OPENING REMAINS IN THE PLEURAL SAC.

He said that this was a physical paradox, which none of the laws either of physics or of physiology could apparently account for. After discussing in detail all the various theories advanced for the explanation of this phenomenon, he showed their weak points, and demonstrated that they did not explain the problem. He considered the power of the normal lung to inflate the collapsed lung by coughing and sudden forcible expiration; but this did not offer a complete explanation, because in such cases the lung should immediately recollapse, which it did not do, and again because, in cases of double empyema with an open-

ing in both pleural cavities, there should be immediate death from asphyxia, while as a matter of fact the lungs expanded under such conditions very well.

DISCUSSION.

DR. NORTHRUP made some animal experiments to determine whether the force of cohesion between the two pleural surfaces was sufficient to maintain the lung in complete expansion, the parietal pleura having been punctured. Samuel West, in his Bradshawe Lecture, 1887, had claimed that such force was sufficient. In five successive operations upon dogs' pleuræ, the lungs collapsed the instant a pin-hole opening was made, thus contradicting the statements of Samuel West. Further experiments were reported, in which a dog's two pleuræ were fitted with double-flanged cannulæ, stoppered with corks. Until the dog recovered from ether the two corks were left in place. When fully recovered one cork was withdrawn, and the dog scarcely suffered dyspnœa on moderate exertion. When both corks were removed, the dog travelled about for two minutes and succumbed to severe dyspnœa, which again entirely disappeared on replacing the corks. Other experiments to determine the behavior of the lungs, the chest having been fully opened, were reported, illustrating the expansive force of strong expiratory effects.

DR. DILLON BROWN, of New York, read a paper entitled

NOISY RESPIRATION IN CHILDREN.

It was a paper on diagnosis, in which the author related a number of curious cases, and after briefly giving an outline of the different diseases in which noisy respiration is a symptom, considered the differential points by means of which a diagnosis by exclusion could be made.

DR. H. KOPLIK, of New York, read a paper entitled

TUBERCULOSIS OF THE TESTIS IN CHILDHOOD.

Including his own case, the author could find in the literature of the subject only twelve cases of primary tuberculosis of the testis occurring in infants and children. The disease in some of these cases was noticed at the birth of the patients, and in others it was clinically diagnosed at the second month, and up to the third year of life. The right testis was the selected organ in most of the cases. In some cases the epididymis, and in others the testis, was first noticed to be the seat of the disease. In one case general tuberculosis followed the testicular trouble, and in another case a secondary cerebral tumor (tubercle) was the cause of death. In some a favorable result is recorded following castration; in others, no such record is made. In four cases the spermatic cord was affected; in one case the disease had spread to the prostate and seminal vesicles. In no case could a traumatism be clearly demonstrated, and in most of the recorded histories the parents were the victims of tuberculosis, thus lending additional support to the theory of a congenital origin. In these cases the author advocated early extirpation, even when the tubercle bacilli could not be satisfactorily demonstrated in the scrapings of a sinus. Delay tended to increase the chances of a return after castration.

The author's case was that of a child aged twenty-two months, with an hereditary history of phthisis. The diagnosis was made by establishing the presence of the tubercle bacilli in the scrapings of a discharging sinus. A return of the disease occurred at the site of the operation after three months. Disease of the other organs could not be established clinically. The diagnosis in these patients is always to be made between syphilis and tuberculosis. The author presented a detailed microscopic examination, histological and bacteriological, of the diseased testis and epididymis in this case. Microphotographs were shown, illustrating the following histological changes: Diffuse tubercle, interstitial changes, acute miliary eruptions both in the testis and epididymis.

DR. FRANCIS HUBER, of New York, read a paper entitled

ACUTE SUPPURATIVE PERITONITIS FOLLOWING VULVO-VAGINAL CATARRH.

The patient was seven years of age, and the symptoms simulated a case of perforation of the appendix. Laparotomy was performed by Dr. Bull, of New York, the abdomen being opened by a lateral incision over the colon. Considerable sero-purulent fluid was found in the peritoneal cavity; the intestines were distended with gas, congested, and here and there coated with lymph. The appendix was perfectly normal in appearance, and no concretions could be detected through its walls. The right Fallopian tube, however, with its extremity, was inflamed, thickened, and evidently had formed the channel by means of which the infecting process had gained entrance into the peritoneal cavity, and thus gave rise to a train of symptoms simulating closely a case of perforation of the appendix. The abdomen was then washed out with hot water, the wound sewed up, and an antiseptic dressing applied. Twenty hours later death occurred from heart failure, the pain and vomiting persisting to the end.

DR. W. P. NORTHRUP, of New York, read a paper entitled

SCLEREMA NEONATORUM; REPORT OF A CASE.

A twin, female, died on the ninth day after birth with typical sclerema of the new-born, as observed in the foundling asylums of Germany and France. Its temperature four days before death was 96½° F. in the rectum. There was subcutaneous hardening where the fat was most abundant about the buttocks and thighs, shoulders and arms, cheeks, and other parts of the body in less degree. The hip- and shoulder-joints became immovable, the knee- and elbow-joints stiff. The child was of a dirty yellow color, hard and cold as though frozen, the temperature gradually descending until it could not be measured on the register of any clinical thermometer. The subcutaneous tissues were examined microscopically and showed no change in either blood-vessels, connective tissue, or fat. The writer had not been able to find more than two other cases occurring in American literature which presented the characteristics so often observed in France and Germany. Many theories had been presented to account for the subcutaneous hardening, but only one offered any satisfaction, and that was the increased proportion of stearine and palmatine compared with oleine always present in children's fat. On exposure to cold in case of a weak foundling, the body-heat might become sufficiently lowered to inaugurate the process of hardening of the stearine and palmatine.

DR. L. EMMETT HOLT, of New York, read a report of a case and presented a specimen of

CONGENITAL MALFORMATION OF THE HEART; COMPLETE ABSENCE OF THE SEPTUM VENTRICULORUM, PULMONARY STENOSIS, AND PATENT FORAMEN OVALE.

The child lived to be eighteen months of age, and died of acute pneumonia, having been under observation for two months. Marked cyanosis had existed from birth. During life the apex-beat was one-half inch to the left of the right nipple, and a loud systolic murmur was present at the apex, but louder at the junction of the left second intercostal space and the sternum, and transmitted toward the left shoulder. It was not heard behind. The normal area of cardiac dulness gave pulmonary resonance. At the autopsy the heart showed: 1. Absence of the septum ventriculorum, the division being marked by only a slight ridge. 2. Very marked pulmonary stenosis, the orifice being about one-fourth inch in diameter. 3. Patent foramen ovale, the opening easily admitting one finger. 4. A shallow pouch, which was the rudimentary left ventricle. 5. A right ventricle, very much hypertrophied, out of which opened both the pulmonary and aortic

arteries, and into which opened both the mitral and tricuspid orifices. The heart was deflected to the right about as much as usually to the left. The border of the right lung was hollowed out for its reception, that of the left being straight.

---

EVENING SESSION, HELD AT THE ARLINGTON HOUSE.

DR. A. V. MEIGS, of Philadelphia, read a paper entitled

THE ARTIFICIAL FEEDING OF INFANTS.

The author said that, after a long experience, he had seen no reason for making any radical change in the artificial food which he had previously recommended. He had found that mother's milk never contained more than one per cent. of casein. This food was based upon the dilution of cows' milk, for the reason that it contains too much casein; the further need of the addition of cream because, in diluting, the fat was reduced to too small an amount; the addition of sugar, to make it equal to the amount contained in human milk; and of lime-water, to change it from being an acid to an alkaline fluid. However, he had fallen upon several improvements to render it easier to get together the required amounts of the different constituents, and thus simplifying the work of the nurses. He directs that instead of taking cream and milk in the proportion, respectively, of two and one in eight, three parts of a weak cream be used, which is obtained as follows: One quart of good ordinary milk is obtained and placed in a high vessel, and allowed to stand in a cool place for three hours. Then one pint is poured slowly from this, care being taken that the vessel is not agitated, the object being to obtain the upper layer of fluid, rich in fat, and leave the lower comparatively poor portion behind. When the child is to be fed, there is taken of this weak cream three tablespoonfuls, of lime-water two tablespoonfuls, and of sugar-water three tablespoonfuls. The sugar-water is to be made in the proportion of eighteen drachms of milk-sugar to one pint of water. This is an improvement upon the food recommended previously by the author, because it is more economical (cream being expensive) and the food is less likely to ferment.

DR. J. A. JEFFRIES, of Boston, read, by invitation, a paper entitled

A CONTRIBUTION TO THE STUDY OF THE SUMMER DIARRHŒAS OF INFANCY.

He held that the cases formed a group or genus of diseases, all closely related, but rarely just alike, and rejected climate, heat, foods, and the like, as direct causes. He then reported the results of his bacteriological examinations of the stools. In these he found thirty-one kinds, but no kind sufficiently often to suggest a specific germ.

The writer then reported a series of experiments upon young cats. Cats fed with pure cultures of the various bacteria remained perfectly well. Cats fed with pure cultures of several kinds in milk contracted summer diarrhœa which ran on to a fatal issue, though the food was changed to fresh milk. The species fed in the milk were rarely found in the intestines. Kittens fed with milk affected by the bacteria, but not curdled, and then sterilized, died in the same way.

From an examination of all the data, he held that the complaint in the kittens was the same as in children, and that it was due to the products of the growth of many forms of bacteria in the food, both before and after consumption. Most bacteria were probably unable to make head against healthy digestion, but flourished if this were disturbed in any way. Probably species not found by him also existed, which were able to thrive without any favoring conditions. Lastly, he pointed out the close relation between summer diarrhœa and that group of symptoms first brought into prominence by Panum—putrid infection. From the therapeutic side, he pointed out that the first thing to do was to keep germs out, and also their products, and that, so far as known, sterile food reduced the number of germs in the stools as much or more than any drug.

Lastly, that it must ever be borne in mind that serious changes were being produced in the intestines, and must be considered apart from all bacteria. Kill every germ in the body, and the eroded and swollen gut must still be attended to.

DR. JOSEPH O'DWYER, of New York, read a paper entitled

CASE OF DIAPHRAGMATIC HERNIA, WITH OPERATION.

The physical signs closely simulated those of an empyema, and a positive diagnosis could not be made until the chest was opened. By removing portions of the two lower true ribs, the false ribs could be pushed down out of the way, and ample room for operation was obtained. After a great deal of difficulty, the intestines were pushed back into the abdominal cavity, and the edges of the opening through the diaphragm, after being refreshed, were brought together and held in place with sutures. The pressure from below on the stitches was so great that it was necessary to keep up counter-pressure from above with a large pad of antiseptic gauze. The child rallied from the operation, but died later on, suddenly, when apparently doing very well. This was the only case on record in which this operation was done. The author exhibited the diaphragm with portions of the chest-wall.

DR. A. CAILLÉ, of New York, reported a case of

PROLAPSUS RECTI, DUE TO LARGE STONE IN THE BLADDER, IN A GIRL OF THREE YEARS.

The patient had been presented at many of the clinics of New York as a case of inveterate prolapse. The gut was usually out two inches, but came down fully seven inches by straining. Micturition was painful, and the urine contained pus. The sphincter ani was relaxed so as to admit three fingers. On careful examination a large stone was found free in the bladder, and removed by suprapubic cystotomy. In extracting the stone the bladder wound was slightly lacerated, in consequence of which the bladder suture leaked slightly on the fourth day. The process of healing took place without fever, and the child was discharged cured in three weeks. The prolapse of the gut was due to the straining caused by the stone in the bladder, and its removal was followed by a complete cure of the prolapse.

---

SECOND DAY—SATURDAY, SEPTEMBER 21ST—MORNING SESSION.

*Held at the Johns Hopkins Hospital, Baltimore.*

DR. H. N. VINEBERG, of New York, read a paper entitled

SOME PRACTICAL POINTS ON THE DIAGNOSIS AND TREATMENT OF MALARIA IN CHILDREN.

The author said that the same vagueness in the diagnosis of malaria in early life was met with as in adult life. There was no good reason for using the term as a cloak of ignorance, for malaria was due to a definite poison and was attended with characteristic symptoms. It was the aim of the writer to bring the most reliable and prominent symptoms under review, and discuss each symptom separately, thereby endeavoring to show its diagnostic value. His remarks were based upon a careful study of eighty cases that came under his own observation, and the perusal of the literature pertaining to the subject.

The signs of acute malaria in early life were chills, convulsions, fever, sweating, enlargement of the spleen, and hæmatozoa in the blood. He carefully analyzed each of these symptoms and their characteristics in malaria, and determined their diagnostic value. He said that the spleen enlarged more rapidly and to a greater degree than in the adult; and that this enlargement was constantly present in the malaria of children. That it must be made out by percussion, and not by palpation as in the adult, because

in early life the enlarged spleen pushed its way upward and backward, and was prevented from descending by the costo-colic ligament, which at that period of life was very rigid. If the dulness did not extend above the upper border of the ninth rib, an accumulation of fæces in the colon should be suspected.

The weight of evidence is in favor of the pathognomonic value of the plasmodium malariæ, but unfortunately it is present only in the more pronounced and severe cases, and is difficult of detection when present.

Chronic malaria was made to include the milder forms of malarial poisoning, which might at first be expressed by acute symptoms, but generally the affection began insidiously. The symptoms in this condition were lassitude, drowsiness, headaches, vertigo, wandering pains in various parts of the body, anorexia, bloody diarrhœa, emaciation, a peculiar tint of the skin, anæmia, urticaria, night-sweats, asthmatic attacks, and pain over the region of the spleen. None of these symptoms were characteristic of malaria, but were also present in a number of other chronic affections. Here, even more than in the acute forms, enlargment of the spleen was a *sine qua non* in the diagnosis of malaria. He called attention to the presence of night-sweats and of attacks of syncope, as symptoms of this condition, which are not mentioned in the literature of the subject.

The treatment of malaria in early life was not the easy matter that some authors led us to suppose. In the acute form, quinine in full doses was most to be depended upon. It was best given in solution with aromatic sulphuric acid and syrup of lemon, or coffee. In private practice the chocolate tablets were valuable. In the chronic variety, it was well to combine the quinine with arsenic. Ergot was found very valuable to reduce the splenic tumors, which often persisted long after the other symptoms had subsided. Pure nitric acid, well diluted, was serviceable in preventing the relapses to which children are so subject.

Dr. Thomas S. Latimer, of Baltimore, showed two

CASES OF SPASTIC PARAPLEGIA.

Both occurred in the same family. In one case the contracted muscles were cut, which gave her marked benefit and improved her walk. In spite of this, however, she is progressively growing worse, and the disease, a cerebral sclerosis, is still active.

Dr. W. D. Booker, of Baltimore, read a paper entitled

A STUDY OF SOME OF THE BACTERIA FOUND IN THE DEJECTA OF INFANTS AFFECTED WITH SUMMER DIARRHŒA (SECOND COMMUNICATION).

This article is the continuation of one read at the Ninth International Medical Congress. It contains a description of 17 varieties of bacteria, isolated from the fæces of 14 children affected with summer diarrhœa.

Bacteria have thus been isolated from the fæces of 30 infants affected with summer diarrhœa, 11 of whom had cholera infantum, 14 catarrhal enteritis, and 5 dysentery. With the exception of bacterium lacti ærogenes and bacterium coli commune, the two constant milk fæces bacteria, no species appear with much constancy, taking the cases as a whole. If the different forms of bacteria are cultivated separately, in the cases classified under the head of cholera infantum, the proteus group has been found in 7 of the 11 cases examined. In the four cases in which no member of this group was found, agar was used exclusively as the separating medium, and in the other case a number of cultures were lost before being identified.

Not only do the proteus bacteria possess in a high degree the power to excite putrefaction; but on account of their extensive and frequent occurrence, they belong to the most important and ordinary putrefactive exciters. The prominent symptoms of the cases of cholera infantum in which the proteus bacteria were found, were drowsiness, stupor, emaciation or great reduction of flesh, more or less collapse, frequent vomiting and purging, with watery and generally offensive stools. Experiments on lower animals with proteus vulgaris and bacillus A. gave about the same results. Bouillon cultures injected into the veins of rabbits caused death in a few hours. There was drowsiness and stupor, and finally convulsions, in all cases; and in some diarrhœa, the latter very profuse in two cases. Cultures directly injected into the intestine, when exposed in a bath of normal salt solution at 38° C., caused active peristalsis. Cultures fed to young animals resulted generally in death, and in some diarrhœa occurred.

The frequent occurrence of this widely spread group of putrefactive bacteria in the most serious cases of summer diarrhœa, in which toxic symptoms are more or less prominent, cannot be without significance. In cases of diarrhœa free from toxic symptoms, no member of this group of bacteria has been found, nor were they found in the healthy fæces of sucklings.

Another species of bacteria which liquefies gelatine and possesses pathogenic properties on lower animals, was found in a large quantity in three cases of cholera infantum and one fatal case of dysentery. In two of the cases of cholera infantum, the proteus vulgaris was also found. These two cases were especially grave, and had decided stupor.

No variety of bacteria appeared to be associated especially with the cases of catarrhal enteritis and dysentery. The fæces in catarrhal enteritis often contained an enormous quantity of bacteria, chiefly varieties of colon bacteria and bacterium lactis ærogenes, with a number of inconstant varieties.

In conclusion, it must be understood that the work is too incomplete to admit of positive conclusions, and as referring to the examination of but a limited number of cases, in which not even all the varieties of bacteria contained in the fæces that can be cultivated on our present nutritive media are supposed to have been separated, and those separated had been but incompletely studied.

Dr. A. Seibert, of New York, read a paper entitled

TWO YEARS OF EXPERIENCE IN THE MECHANICAL TREATMENT OF GASTRO-INTESTINAL DISORDERS IN INFANTS.

He said that, as we now admit that these affections are caused by bacteria and chemical poisons getting into the digestive organs of the children, it appears but rational to follow the first logical therapeutic indication, and empty the stomach and intestines of these noxious substances. The profession, here and abroad, has been too conservative in following this imperative and clear indication. Calomel and castor-oil do not cleanse sufficiently. Epstein's method of stomach washing in infants, and Baginski's proposed bowel washing in all cases of diarrhœa, have long been overlooked entirely, and are still ignored by the majority of practitioners. Seibert reports on 1,404 cases of gastro-intestinal disorders in children under three years, treated within the last two years. Stomach washing was done in 521 cases, and bowel washing in 1,309 cases. The majority of the cases in which stomach washing was employed suffered from acute gastro-intestinal catarrh, nearly all of a severity to produce more or less pronounced collapse. Of these 6 died. Besides, cases of entero-colitis with true intestinal inflammation were treated by both methods, and also all cases of chronic gastro intestinal catarrh. All cases of diarrhœa, whether mild or severe, were treated by bowel washing. In all cases of infantile dyspepsia the stomach was washed.

MORTALITY.

Acute gastro-intestinal catarrh, about five hundred cases with six deaths. Entero-colitis with peritonitic irritation, eight cases with six deaths. Chronic gastro-intestinal catarrh (with atrophy and marasmus), about one hundred with one death (in this case the mother had tuberculosis). In cases of acute simple diarrhœa, including follicular en-

teritis, no deaths occurred. The youngest child stomach washing was practised on was a day and a half old, the author's own baby. All children felt better after stomach and bowel washing. Collapse in cholera infantum is the strongest possible indication for stomach washing; the deeper the collapse, the sooner the stomach and bowel ought to be cleansed. The writer never saw collapse get worse after washing, and never had any accident.

The following papers were read by title: "Aneurism in Early Life," by Dr. A. Jacobi, of New York; "Scarlet Fever," by Dr. I. N. Love, of St. Louis; "Recent Improvements in Infant Feeding," by Dr. J. Lewis Smith, of New York; "Two Cases of Hepatic Cirrhosis in Children," by Dr. M. P. Hatfield, of Chicago; "Notes on a Case of Ataxia in a Child of Ten Years," by Dr. A. D. Blackader, of Montreal; "Carpo-pedal Contractions, One Manifestation of Tetany," by Dr. C. W. Earle, of Chicago; "Two Cases of Nystagmus Associated with Choreatic Movements of the Head in Rachitic Babies," by Dr. A. Caillé, of New York; "A Case of Simple Muscular Atrophy of the Facio-scapulo-humeral Type," and "Cerebral Sclerosis in Children," by Dr. William Osler, of Baltimore.

The following officers were elected for the ensuing year: *President*—Dr. J. Lewis Smith, of New York; *First Vice-President*—Dr. A. V. Meigs, of Philadelphia; *Second Vice-President*—Dr. F. Forchheimer, of Cincinnati; *Secretary*—Dr. W. D. Booker, of Baltimore; *Recorder*—Dr. W. P. Watson, of Jersey City; *Treasurer*—Dr. C. W. Earle, of Chicago; and *Council*—Dr. T. S. Latimer, of Baltimore, Dr. J. M. Keating, of Philadelphia, Dr. I. N. Love, of St. Louis, Dr. S. C. Busey, of Washington, Dr. C. P. Putnam, of Boston, Dr. A. D. Blackader, of Montreal, and Dr. L. E. Holt, of New York.

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 29 to October 5, 1889.*

ADAIR, GEORGE W., Captain and Assistant Surgeon. Leave of absence granted for one month. S. O. 90, Headquarters Department of the Platte, September 25, 1889.

POINDEXTER, JEFFERSON D., Assistant Surgeon. Granted leave of absence for one month. S. O. No. 113, Headquarters Department of Dakota, September 30, 1889.

POPE, BENJAMIN F., Surgeon. Relieved from duty at Fort Clark, Tex., and will report for duty to Commanding Officer, Whipple Barracks, Arizona Ter. Par. 11, S. O. No. 230, A. G. O., October 3, 1889.

BILLINGS, JOHN S., Surgeon. Detailed as delegate to represent the Medical Department of the Army at the annual meeting of the American Public Health Association, to be held at Brooklyn, N. Y., October 22, 1889. Par. 10, S. O. No. 230, A. G. O., October 3, 1889.

TREMAINE, WILLIAM S., Surgeon. Relieved from temporary duty at Fort Leavenworth, Kan., and will return to his home (Buffalo, N. Y.). Par. 13, S. O. No. 230, A. G. O., October 3, 1889.

KENDALL, WILLIAM P., Assistant Surgeon. Granted leave of absence for one month. S. O. 93, Department of the Platte, October 2, 1889.

---

*Official List of Changes in the Medical Corps of the United States Navy for the week ending October 5, 1889.*

HARMON, GEORGE E. H., Surgeon. Detached from the U. S. S. Constellation, and ordered to Naval Academy.

LOWNES, C. H. T., Assistant Surgeon. Detached from the U. S. S. Constellation, and ordered to Naval Academy.

WINSLOW, GEORGE F., Surgeon. Ordered to Marine Rendezvous, Boston.

HENRY, CHARLES P., Assistant Surgeon. Ordered before the Retiring Board for examination.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 5, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 62 | 14 |
| Scarlet fever | 40 | 5 |
| Cerebro-spinal meningitis | 2 | 2 |
| Measles | 23 | 2 |
| Diphtheria | 61 | 13 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

THE PATHOLOGICAL BEARINGS OF HEREDITY.—Animals, including man, have arrived at their present state of development by the combined, but rival, forces of heredity and evolution, the latter term including the effects of surrounding environment. Evolution without heredity, as Ribot observes, would render every change transitory, and every modification, whether beneficial or not, would disappear with the individual. The results of heredity without evolution, on the other hand, would give us the monotonous conservation of the same types fixed once and for all. With heredity and evolution we have life and variation. Evolution produces physiological and psychological modifications, habit fixes these in the individual, and heredity fixes them in the race. These aphorisms apply as well to diseased conditions as to health, and in endeavoring to unravel the mysterious bearings of heredity upon disease we have to bear in mind the conflicting influence of stability with this tendency to variation. The operation of hereditary tendencies is perpetually disturbed by innumerable circumstances unappreciable by our means of observation, but capable nevertheless of producing varieties infinite alike in extent and degree. It is well known that sensitiveness, whether to general or special impressions, varies extremely in different individuals. An operation which involves pain amounting to agony to one person will be borne by another with comparative indifference, and the tissues of one person will react to stimuli to such an extent as to cause violent inflammation, while those of another prove quite passive under similar circumstances. It is this varying irritability which explains the fact that no two cases are exactly alike of the same disease. These differences are distinctly transmissible from parent to offspring, and when the inherited quality is a tendency on the part of certain tissues to react more readily than normal to morbid influences, we say that a person has a diathesis. What we term, for the want of a better word, idiosyncrasy, is in reality a diathesis or part of a diathesis—a peculiar susceptibility of the individual to react unduly, either in excess or otherwise, to certain stimuli. Idiosyncrasies may be transmitted, as they very frequently are, but they are in any case congenital. These peculiarities of tissue and function often remain latent until some morbid process emphasizes the fact that a particular proclivity exists in the individual. We cannot better illustrate this point than by quoting the well-known story, that of several hunters who were thrown at the same time into the same stream of water, no two were affected alike. In one an attack of rheumatism marks the tendency of joint-tissues

to take on a certain process of inflammation. In another an attack of inflammation of the lungs points out the pulmonary apparatus as the organ least endowed with powers of resistance, while a third simply gets a cold in the head. As for the horses, they very probably escape scot free in the absence of any special or general variation in the tissue tendencies. While we recognize clearly enough that certain diseases are largely influenced by inherited tendencies, there are others, and these the majority, in which the influence of heredity is more or less indistinct, but it is as certain as anything of the nature of a deduction can be that the conduct of a particular organism, in the face of morbid influences, is determined largely by inherited qualities of tissue, even when the susceptibility is difficult or impossible to make out. The problem before us is to discover and elucidate the natural laws which govern and regulate the transmission of mental and physical qualities, or, in the words of Mr. Lewis, "the paths along which forces travel to their particular results." We are already in possession of a large number of facts and observations bearing upon the "how," though the "why" still remains, and is likely to remain, unfathomable. These relative individual differences of bone tissue-cell, organ, membrane, and vessels, which are admitted by all competent authorities, really form the foundation of all sound views in pathology, and the more they are recognized and appreciated the more will the art of medicine acquire scientific exactitude and increased usefulness to humanity. In the words of Sir James Paget, better treatment will follow better diagnosis, and better diagnosis will certainly follow a more exact pathology.—*The Medical Press.*

Immediate Relief of Hoarseness.—The first Napoleon is said to have been subject to sudden attacks of severe hoarseness, for the immediate relief of which his physician was in the habit of prescribing the following, known as Foreau's syrup:

℞. Liquor ammoniæ fortioris ..... ..... ♏ x.
Syrupi erysimi..... ..... ʒ iss.
Infusionis tiliæ florum..... ʒ iiss.
M. To be taken at one dose.

Erysemum officinale (*sisymbrium offic.*), or hedge mustard, is no longer officinal, but is easily obtained. It is a small annual growing almost everywhere in the United States and Canada, as well as in Europe. The infusion of linden (tilia) is used simply as an agreeable vehicle, and may be dispensed with or supplanted by any other pleasant vehicle.—*St. Louis Medical and Surgical Journal.*

An Historico medical Coincidence.—In Rome, where the Sacred Way descends into the Forum, stands the interesting old church dedicated to Saints Cosmas and Damianus, two Christian physicians who for their services and sufferings in Arabia were canonized by the Pope. Damianus, or, as he is called for brevity's sake, Damian, became a power in Italy, where more than one house of prayer was reared in his honor, notably that one in the Umbrian hills. It was there that St. Francis of Assisi devoted himself to the spiritual life, and in a special manner to the cure of leprosy, a disease which by that time (the latter half of the twelfth century) had been introduced by the Crusaders from the East into all the countries washed by the Mediterranean. A ritual was compiled to celebrate with awful solemnity the isolation of the leper from his fellow-Christians—"a pathetic and melancholy service, in which the sternest interdict was softened by words of consolation and pity." Moved by their forlorn condition, St. Francis became the constant associate of the leprous and the inmate of their asylum at Assisi, where he washed their feet and dressed their sores—to which, indeed, in one case he applied his lips with such effect that the poor leper instantly became whole. So, at least, says St. Bonaventura. But the interesting point is this: that his care and cure of these victims to a loathsome malady was practised "sub invocatione Sancti Damiani" (under the invocation of St. Damian), a saint who six centuries thereafter was to find a counterpart in a Belgian priest of almost identical name—the Père Damien, whose noble life and death in the leper island of Molokai will never fade from the annals of his church, or, indeed, from the history of the world. The Vatican, it is understood, has taken the preliminary steps toward the canonization of this true martyr in the service of mankind, and though the prescriptive period required for admission into the saintly calendar will not expire till well on into the twelfth century, there may be those now living who will survive to witness the Church of Rome's invocation of St. Damienus, closely allied in merit as in name with that other St. Damianus, who inspired St. Francis to his life of philanthropic self-sacrifice.—*The Lancet.*

Chicha Poisoning.—The *Anales de la Instrucción Publica en la Republica de Colombia* contain an interesting account of the effects produced by over-indulgence in a certain popular drink called "chicha," which is prepared by the fermentation of malted maize, with the addition of the leaves of the primum payaca, or "sandino," as it is called in the country. This beverage, when taken in excess, produces a feeling of extreme weariness, rendering the patients totally unfit to follow any kind of employment. There is also observed a loss of the power of co-ordination, which may make it possible on a cursory inspection to mistake the case for one of locomotor ataxia or spasmodic tabes; but "chichinism" can be distinguished from these conditions by making the patient shut his eyes and stand or walk, and touch his toes with his hands, all of which he is able to do. The course of chichinism, too, is quite short, and it may terminate in trophic changes and acute diffuse myelitis. Another symptom which is frequently observed is an erythema of the dorsum of the hand, similar to that seen in pellagra. Physiological experiments also show that the chicha has a special action on the skin; for frogs subjected to its influence present very decided changes of color. With chronic alcoholism there is a good deal of affinity, but there does not seem to be any liability to excitement or hallucinations.—*The Lancet.*

The Dread of Death.—Sir Lyon Playfair, in a letter to Junius Henri Browne, author of a paper with the above title, says: "Having represented a large constituency (the University of Edinburgh) for seventeen years as a member of Parliament, I naturally came in contact with the most eminent medical men in England. I have put the question to most of them, 'Did you, in your extensive practice, ever know a patient who was afraid to die?' With two exceptions they answered 'No.' One of these exceptions was Sir Benjamin Brodie, who said he had seen one case. The other was Sir Robert Christian, who had seen one case, that of a girl of bad character who had a sudden accident. I have known three friends who were partially devoured by wild beasts under apparently hopeless circumstances of escape. The first was Livingstone, the great African traveller, who was knocked on his back by a lion which began to munch his arm. He assured me that he felt no fear or pain, and that his only feeling was one of intense curiosity as to which part of the body the lion would take next. The next was Rustem Pasha, now Turkish Ambassador in London. A bear attacked him, and tore off part of his hand, and part of his arm and shoulder. He also assured me that he had neither pain nor fear, but that he felt excessively angry because the bear grunted with so much satisfaction in munching him. The third case is that of Sir Edward Bradford, an Indian officer now occupying a high position in the Indian Office. He was seized in a solitary place by a tiger, which held him firmly behind the shoulders with one paw and then deliberately devoured the whole of his arm, beginning at the end and ending at the shoulder. He was positive that he had no sensation of fear, and thinks that he felt a little pain when the fangs went through his hand but is certain that he felt none during the munching of his arm.—*The New Idea.*

### A PATHOLOGICAL CONDITION OF THE LUNGS, HITHERTO UNDESCRIBED IN THIS COUNTRY, BUT WHICH IS NOT INFREQUENT.

BY F. PEYRE PORCHER, A.B., M.D.,

ONE OF THE PHYSICIANS TO THE CITY HOSPITAL, CHARLESTON, S. C.

DURING the course of a very prolonged service in hospitals I have repeatedly observed a condition of the lungs which is markedly distinct and characteristic, which I have not seen described. I speak of it at present only as a pathological condition, leaving it to others to decide whether it should take rank as a distinct disease.

Certain patients presented the following symptoms: Dulness, or subdulness, generally at the middle, lateral, or posterior portions of the chest; there was always imperfect respiration; scarcely any râles were present, or if so, they were sparsely disseminated, and generally the subcrepitant; or, perhaps, in lieu of râles there was only rough breathing. The condition was consequent on antecedent morbid states, and there was not necessarily elevation of temperature; there did not exist evidence of any acute inflammation, or any of the well-known classic diseases of the chest—no phthisis, pneumonia, bronchitis, pleurisy, emphysema, hydrothorax, etc. The positive physical signs of these several diseases were all absent—there was no crepitant, or sibilant, or crackling râles; neither was there pain nor rubbing sounds. So all the diseases which these signs indicated had to be excluded, and a name was wanted for the new condition which had been isolated.

But to continue the citation of positive and negative symptoms: The respiratory murmur, though not normal, was not completely absent, for the lung was still pervious to air; the vocal resonance—or what I prefer to term the reverberation of the voice—was slightly affected; some complementary respiration might be present, but this was not very decided, because there was no absolute consolidation; scarcely any dyspnœa may exist, and the cough may be moderate or absent.

Constantly, also, when an autopsy was afforded in such cases, the physical evidences of the diseases above cited were absent, *and there was invariably present a large amount of bloody serum exuding from the cut surfaces, and it would flow most freely when the lung was squeezed.* Here was plainly a gross morbid fact, which had to be noted and accounted for.

No disease of the heart coexisted, to the obstruction produced by which might be ascribed the collection of bloody serum; and though I have not yet been able to associate the two, I would not be surprised if cases were found to be dependent upon diseases of the heart.

In a hepatized or in a solidified lung the dulness is complete, and there is bronchial, and often puerile, respiration in the healthy areas, so that hepatization and solidification were also excluded. It was not œdema, for this is general over both lungs, and Laënnec had taught us that the crepitant râle is as characteristic of œdema as it is of pneumonia. I have heard, as it were, a shower of fine crepitation over the entire lungs in a case of œdema consequent upon measles; the œdema was detected by means of the râles. The crepitant râle was not present, nor the fever, etc., essential to pneumonia; neither was there any rusty-colored sputa.

The conditions with which our cases would be most likely to be confounded would be the hypostatic congestion, or the hypostatic pneumonia of recent authors—if such a disease exists. But these will be referred to again.

I long since began to designate the condition, or disease, referred to as "Engorgement of the Lungs"—serum being always mixed with blood. I was compelled to use these terms, because they were true and applicable, and were essential in describing and interpreting the condition. I felt satisfied that others must frequently encounter a like pathological state, especially in hospitals; but I could get no response or support from authorities in this country. I wrote to Professor Austin Flint upon the subject years ago. The loss of his letter is regretted, together with the notes of cases with autopsies, though I possess the record of one observed in 1879, and had been observing and demonstrating the condition long anterior to that period. Some illustrative cases will be inserted at the conclusion of this paper.

My cases of engorgement of the lungs exist for days and weeks, and do not depend wholly upon the accidencies of position, stasis of the blood, age of patient, or want of vitality. The powers of life are not specially enfeebled. They do not seem to depend on Bright's disease, dropsy after scarlet fever, measles, infectious diseases, etc.—as is the case with congestion of the lungs and œdema. I did not for a moment dream of calling them hypostatic congestion—certainly not in the old sense of the use of the term, for the condition is not necessarily hypostatic in cause.

The term infiltration is not very inapplicable, and the diagnosis may be attended with difficulty; but I have seen lungs infiltrated after severe pneumonias, and tubercular infiltrations exist; but in neither case is there often a large flow of serous fluid when the lung is cut, as is constant in engorgement of the lungs. This I have repeatedly observed in autopsies—some of them quite recent, and examined with a view to determining this question. Yet I have also recently seen serum with bloody and purulent matter exuding from the lungs in a well-marked case of general tuberculosis. The presence of fever, purulent expectoration, rise of evening temperature, and other signs of tuberculosis must be used to aid in their distinction from engorgement of the lungs.

I consulted, almost accidentally (1888), Ziemssen's "Cyclopædia," vol. v., "Diseases of the Respiratory Organs." In Juergensen's paper therein, entitled "Hypostatic Processes of the Lungs" (p. 236), I found that I was supported by one writer, he a master-mind (M. Piorry); and the simple fact may now be stated that I had indicated a diseased condition besides those usually recognized by the profession; and this had in a great measure corresponded with what Piorry has pointed out as a distinct form of disease, to be recognized and treated by the general practitioner. I had noticed and had endeavored to attract attention to a most marked and characteristic morbid condition, which physicians in hospital practice must have met, and must now meet, but failed to recognize, name, and separate from others.

Juergensen writes as follows, *loc. cit. sup.*: "Hypostatic pneumonia and hypostatic conditions of the lungs were first recognized as a *distinct form of pulmonary diseas* through the labors of French writers. Pre-eminent among them is Piorry, who handles the subject with great clear-

ness, and whose teachings are based upon a rich experience. He likewise gave the disease its name."

"Piorry proved by experiment that a hypostatic condition diagnosticated during life did not alter its location after death, under the laws of gravitation. As Piorry made his diagnosis long before death, it was evident that this condition did not result during the death-struggle. By means of these experiments *hypostasis ceased to be a condition of but little pathological significance.* If it occurred during life, then it must have an influence on life."

To quote still from Juergensen: "Does an *inflammation of the lung* actually exist? Is the term 'hypostatic pneumonia' correct? Here we must agree with Piorry, who answered this question in the negative in his nomenclature, and afterward still further confirmed this opinion." "He calls this form of disease *pneumonémie hypostatique*, and gives as a synonyme *engouement pulmonaire*" (vol. v., p. 238).

So I am sustained by Piorry, not only as regards the existence of a special disease and in the non-existence of an inflammation of the lung, but also in the use of the identical designation *engouement pulmonaire*, which may be equivalent to "engorgement of the lungs."

*Pneumonémie*, under Piorry's peculiar phraseology, it will be observed, is not to be confounded with pneumonia; it is equivalent to congestion. Juergensen, in going on to describe "*the conditions which give occasion to the rise of hypostatic infiltrations of the lungs*," makes no difficulty whatever regarding the existence of the condition, but describes its pathological anatomy, symptomatology, etc.

I need only quote the following, which may be compared with my own observations: "The *local symptoms* of hypostasis *demonstrable by physical examination* are the following: At first diminished resonance on percussion, beginning at the lower angle of the scapula, and on auscultation a lessening, sometimes almost a cessation of the respiratory murmur, which is vesicular, or may be quite indefinite in character. At the point of attack the vocal fremitus is weak. If hypostasis is complicated with a coexistent catarrh, new features foreign to the former disease will appear. Mucous râles, for example, are usually absent in simple hypostasis. The dulness on percussion and the auscultatory signs, as a rule, extend slowly from *below upward.* There is a period at which absolutely no breathing is to be heard over the consolidated portion (Piorry). Then mucous râles gradually become audible, those in the larger tubes appearing first. In case of a fatal termination extensive œdema of the lungs supervenes, accompanied by the auscultatory sign peculiar to that condition." I have not been able to confirm the supervention of œdema; certainly never got the crepitant râle, or other signs of œdema, just before death, nor at any period.

However, both of us recognized and marked out a collection of symptoms which are often found associated, but which had not previously been designated as characterizing a special diseased condition. This collection can have no other name than Engorgement of the Lungs; and all such terms as pneumonias, in any form, hyperæmias, œdemas, etc., must be rejected, as I will endeavor to show later on.

The merit of Piorry consists in his freeing hypostatic processes from the imputation—ancient and deep-grounded in all writings—of occurring only just before death; and giving it its true place as a diseased condition of variable duration, to be recognized during life. What he has done we have just read from Juergensen's paper.

If my cases of engorgement of the lungs were proved to be only forms of hypostasis, yet I also recognized them as unconnected with position, or with the death-struggle; as existing, and to be studied and treated long before dissolution. But I do not regard "engorgement of the lungs" as dependent altogether upon hypostasis, therefore my observations do not conform strictly to Piorry's.

Woillez, in his "Dictionnaire de Diagnostique médicale," Paris, 1870, citing "the diseases of the lungs which can be diagnosticated during life," does not even refer to such a disease; he includes only: Congestion, Pulmonary Apoplexy, Pneumonia, Gangrene of the Lungs, Œdema, Tubercles (Phthisis); Lardaceous Degeneration, or Amyloid; Cancer, Hydatid or other Tumors, Vesicular Emphysema, Accidental Perforation of the Organ (Pneumothorax).

I quote one passage from his rather elaborate description of "Congestion of the Lungs," to show how far removed this also is from the disease we are considering:

"*Congestion du Poumon*: 1°. *Éléments de la diagnostique*, considérée comme maladie au même titre que la bronchite franche et la pneumonie; l'hypérémie pulmonaire débute subitement par une douleur du côté de la poitrine, avec fièvre le plus souvent légère, parfois intense, une dyspnée très variable, avec *absence de toux*, ou *toux assez rare*, sèche ou suivie *d'expectoration muqueuse*, transparente, parfois un peu teintée de sang."

All he has to say under the head of Engorgement ("Engouement") is as follows: "This word is applied principally to the lungs and to the intestines. It expresses in the first case a state of inflammatory congestion still ill defined." This was in 1870.

Professor John Guitéras, late of this city, informs me that Woillez has recently (1889) written a paper on "The Acute Diseases of the Chest," published in one of the New York medical journals, with six cases of acute fatal congestion of the lungs from exposure to cold.

In view of the claims which I have ventured to make, the burden of proof is upon me to show that engorgement of the lungs as a disease, though not infrequently met with, is not described or recognized by the prominent authors in this country. One or two of these must therefore be examined.

But first, as to the literature of the subject in this country. All that we have is a paper by the present writer (which had wholly passed out of his mind) published in the *American Journal of the Medical Sciences* for October, 1869, being one section[1] of an article entitled "Certain Pathological Conditions."

It is true that the so-called "hypostatic pneumonia" has been referred to in the edition of 1886 of "Flint's Practice," by Flint, Jr., and Welch, but this is a comparatively recent publication. The existence of such a disease is regarded as problematical.

Flint writes as follows: "Passive hyperæmia occurring in the dependent portions of the lungs is called hypostatic

[1] This being brief, I insert here, as follows:

*Frequency of Serous Engorgement of the Lungs.*—I have very frequently met with a condition of the lungs which I have been in the habit of designating in my clinical teaching before students as "serous engorgement," or simply pulmonary engorgement.

The lower lobes on either side are the parts usually implicated. There is some dulness on percussion, some deep-seated respiration, with rough breathing, and at times a little crepitation. Coexisting with such a condition there is neither pneumonia, bronchitis, tuberculosis, phthisis, nor any cavity. The post-mortem examinations have repeatedly disclosed the unmixed character of the pathological state.

It is a result of neglected catarrhs, previously existing bronchitis or pneumonia in a chronic form, and sometimes the engorgement is partly hypostatic; but this term should be reserved for post-mortem changes, or those occurring just before death. I think the term used above can often be safely and properly used as a distinctive one, marking a substantive condition. The term "congestion" should be applied only to active determination of blood to the lungs, as in apoplexy, etc. In "serous engorgement" there is often a large amount of serous fluid mixed with air, which escapes on cutting into the lungs, and the dulness is not absolute when the patient is examined before death, as the lung tissue is still partly permeable to air.

This serous engorgement often also accompanies tuberculosis of the lungs, as, for example, when cavities or granular tubercular matter is found in the upper portion of the organs, the lower and more dependent portions are simply engorged with serum, and furnish corresponding auscultatory and percussional signs. But the morbid alterations referred to as existing at the base or more dependent portions of the lungs are not "tubercular infiltrations," which almost always have their seat under the clavicles.

If "serous engorgement" is one and the same with "œdema," then it exists much more frequently than the books would teach us to believe it does, and Laennec was wrong in stating that the crepitant râle characterized three conditions, namely: The forming stage of pneumonia, the congested tissues around a hemorrhagic spot, and œdema (in which he is correct as far as my experience goes), for in the serous engorgement described above the crepitant râle is rarely if ever heard. In true "œdema" of the lungs consequent upon measles, the crepitant râle is heard over the entire region of the chest.

congestion. The conditions which favor the production of hypostatic congestion are enfeebled heart's action and the maintenance of the body in one position for a long time. It is met with in acute infectious diseases, in the aged, and in the course of chronic diseases which occasion general debility. The higher grades of hypostatic congestion result in a transudation of bloody serum. The condition of lung thus produced has been called splenization. . . ."

Now, our cases are not pneumonias—there is no true splenization, they did not necessarily depend upon acute infectious diseases, did not exist in the aged; the term congestion is not applicable, as I have shown, nor were they dependent upon debility, as before stated. References also to these points have apparently only been made in editions of recent years.

Professor S. C. Chew has an able paper, written in his usual style of excellence, in vol. iii. of Pepper's "System of Medicine," entitled "Congestion and Œdema of the Lungs (Hypostatic Pneumonia)." What is said below will include all the arguments I have to offer in the effort to show that he also does not include Engorgement of the Lungs in the subject-matters treated by him, and I refrain from a minute analysis only on account of want of space.

The work on "Practice," third edition, 1885, by so deservedly conspicuous an authority as Dr. Loomis, must also be examined; but having the greatest respect for his character, ability, and experience, I write in no undue critical or controversial spirit. The terms "engorgement," or "serous engorgement," are nowhere found, either in the index or in the body of the work; nor is there any other disease referred to by him which can be confounded with "engorgement of the lungs," as I will endeavor to show by a careful analysis.

The nearest approach thereto will be discovered in the section entitled "Hyperæmia of the Lungs," which is divided by Loomis into "Active Hyperæmia, or Fluxion, and Passive Hyperæmia, or Pulmonary Congestion."

With the first, active hyperæmia, our disease, "engorgement of the lungs," will not be confounded. The second, passive hyperæmia, embraces a subdivision, viz., hypostatic congestion, which somewhat resembles "serous engorgement," but if the diagnostic differences are closely scanned, the incompatibilities can readily be exposed. In justice to the author we quote as follows (p. 113):

"*Passive hyperæmia* or *pulmonary congestion* depends upon an obstruction to the return circulation. It occurs with varying appearances and anatomical characteristics that have led to its subdivision into *splenization*, *brown induration*, and *hypostatic congestion*. A form of *active* hyperæmia has, because of its physiological cause and situation, been called *compensatory hyperæmia*. Other divisions are sometimes made, but all the varieties can probably be classified under these heads."

I have explained elsewhere why "engorgement of the lungs" cannot be confounded with *splenization*, with *hypostatic*, or any other active *congestion;* still less is it possible to confound it with "brown induration," or "compensatory hyperæmia"—this will be admitted without hesitation by everyone. But I must recur to "hypostatic congestion." This, unless in a modern and changed sense of the term—and Loomis fails to say that views have changed with regard to it—is not to be confounded, as I explained, with "engorgement of the lungs;" unless it is assented to that hypostatic congestion (laying aside for the present any objection to the term congestion) is not necessarily associated with the position of the body or with post-mortem changes, as Piorry's researches have proven. It is still a grave misnomer to apply the term hypostatic to a disease where there is no necessary hypostasis. If the characteristics are abandoned which make it a case of hypostasis, then we had better change the name for one more appropriate, and call the disease engorgement of the lungs, which is far the most applicable, as it is descriptive of the true condition. But, finally, our "engorgement of the lungs" is not *hypostatic congestion!* and Piorry himself called his hypostatic congestion "*engouement pulmonaire.*" He encountered the same diseased condition that I did, and the difficulty was met in each case by the application of analogous terms.

Let us see what the learned author (Loomis) says of "hypostatic congestion"—I quote *verbatim et literatim:* "*Hypostatic* congestion is a term applied to that form of hyperæmia which occurs in the most dependent parts of the lungs; it is usually bilateral in those dying of diseases which have confined them to bed for a long time. It very closely resembles splenization, but the lung-tissue is very friable instead of doughy, and the little whitish or reddish points which are seen in splenization are absent in hypostatic congestion. The lung-texture itself is but little altered. Low forms of pneumonia are liable to occur in hypostatic congested parts of the lung, and hence some call it 'hypostatic pneumonia,' and others again call it splenification (differing from the above described splenization)."

Our disease has nothing to do primarily or essentially with hypostasis, nothing to do with being "confined in bed for a long time;" there is also no splenification; it has nothing to do with any form of pneumonia. The crepitant râle, fever, or rusty-colored sputa—one or more—should be essential to every morbid state to which the term pneumonia is applied. I have repeatedly stated that none of these symptoms characterize engorgement of the lungs. Besides, the description by the able pathologist quoted above is entirely too inadequate; there is not enough relating to the morbid anatomy, symptomatology, etc., of hypostatic congestion to prove that it agrees with "engorgement of the lungs," and hence that the latter is no new disease.

As I have satisfactorily disposed of the subdivisions of "passive hyperæmia," I might well be dispensed from considering the characteristics of passive hyperæmia itself. But I will state that this is not to be confounded with "engorgement of the lungs." Loomis gives some of the characteristics of passive hyperæmia by which the identity of the two will be proven to be irreconcilable. For example, he does not mention serum as exuding, but only "dark blood;" "bronchial tubes and pleura show *post-mortem staining*." "Engorgement of the lungs" has nothing to do necessarily with post-mortem staining; it is not dependent upon the position of the body—for a long or a short period; or upon the accidencies of dissolution—upon recumbency or decubitus; it bears no relation whatever to death or the death-struggle—it has, indeed, existed for weeks or months before death.

In "engorgement of the lungs" there is serum and blood mixed—so the term *hyperæmia*, also, would, for this reason, not be comprehensive enough.

Here are some cogent additional reasons: Dr. Loomis, in speaking also of the different varieties of pulmonary hyperæmia (p. 115), says, "blood-stained, watery expectoration is the prominent objective symptom of pulmonary congestion. The advent of *active* hyperæmia is usually very sudden."

I have already shown that "engorgement of the lungs" is not congestion; and also that it is never active and sudden in its onset—as is congestion. In "engorgement of the lungs" "watery expectoration is not a prominent symptom." In fact it does not exist in cases of engorgement of the lungs.

Dr. Loomis again repeats (p. 116) that the "diagnosis of pulmonary congestion is not difficult if one considers the circumstances under which it occurs, and the two prominent symptoms, viz., the dyspnœa and the copious, watery, blood-stained expectoration." He also says that "œdema" is characterized by "blood-stained sputum" (p. 116).

These admissions by a pathologist of great experience settle the question that neither of these diseases is synonymous with "engorgement of the lungs," in that blood-stained sputum has not been seen by myself in the latter,

nor referred to in the statement of the pathology of the diseased condition with which the researches of my old master, Piorry, have been so promiently associated.

*Résumé.*—The pathological condition referred to should be best designated and known as *Engorgement of the Lungs;*

Because, 1st, *Engorgement of the lungs* may include *blood and serum*, both being invariably present.

2d. Term "*hypostatic*" objectionable; because condition does not depend on hypostasis.

3d. "*Congestion*" objectionable; because congestion is an acute condition (see body of paper).

4th. "*Hyperæmia*" objectionable; because it necessitates the presence of blood, and does not include serum, which is always present.

5th. "*Pneumonia*," or "*pneumonic*," objectionable; because the crepitant râle, fever, rusty-colored sputa, bronchial respiration, and hepatization, are all *absent*.

6th. "*Œdema*" objectionable; because "in œdema the expectoration is always frothy and watery in character and abundant" (Loomis), and there is dyspnœa. These do not occur in engorgement of the lungs, and in the latter there is, also, no blueness of lips, lividity, cold extremities, etc., as are found in extreme cases of œdema.

*Illustrative Cases.*—During the past year the following (which was a tolerably fair specimen, but the records are meagre) occurred during my attendance upon the Marine Hospital wards:

Case I.—E. O——, white, aged thirty, admitted August 7, 1888, with a diagnosis of bronchitis. Evening temperature, 100° F.; morning, 98⅘° F. His condition was as follows: Dulness over front of right lung; left lung resonant; no râles; vocal resonance almost amounting to pectoriloquy in the right lung posteriorly, above the scapula. No indication of phthisis, fibroid phthisis, bronchitis, or pleurisy.

*Diagnosis.*—"Engorgement of the lungs."

*Note.*—Similar symptoms naturally occurred in a man who died from drowning a few days previously.

August 11th.—Revulsives were employed; much less dulness observed at the base of right lung anteriorly and posteriorly; temperature ranges from 97° to 101° F. From physicians present, when invited to express their opinions based on a consideration of the symptoms, the replies varied, as follows: "Incipient phthisis," "Catarrhal pneumonia," "Hypostatic congestion," "Œdema," etc.

There had been no evidence of catarrhal symptoms or pneumonia, no crepitant râles, rusty-colored sputa, etc. Hypostatic congestion was the closest approach; but this, as we then interpreted it here, is a condition characterizing the very latest ante-mortem state, results from a protracted recumbency upon the back, occurs in the aged or when the powers of life are enfeebled. It was not congestion of the lungs, for attacks of this are sudden and violent, and there is active hyperæmia.

The next case is extracted *verbatim* from my notes, under the date 1879, and therein entitled "serous engorgement," which term was used here as synonymous with "engorgement of the lungs."

Case II.—Woman, colored, aged fifty, entered hospital October 5, 1879. Complained of some derangement of chest and stomach; no active disturbance of stomach; enlarged liver, which was hard; no fever or dyspnœa; cough, but no expectoration; dulness over heart; resonance over apices of both lungs, but at back of right and left lung partial dulness, with subcrepitant râles, especially in right lung; dulness more marked at inferior margin of lungs.

*Diagnosis.*—"Serous engorgement;" possibly water in pericardium, but no pleuritis.

Death occurred rather suddenly—subject complaining of oppression of the chest; pulse normal. All the post-mortem phenomena corresponded with the diagnosis.

*Autopsy.*—Above thoroughly sustained, as follows: Fluid in pericardium; liver large, hard, thickened; spleen medium size. Right lung engorged, and poured out serum when cut; dilatation of right ventricle and general enlargement of the heart, no special valvular disease; veins of right side of the neck enlarged—the jugular was more than an inch in diameter.

*Note*, 1879.—I make a distinction between "engorgement," congestion, and also œdema—the justness of which this case confirmed. Drs. Rhett, Andrews, and Wanamaker, house physicians, were present.

Case III.—A. K——, colored, aged twenty-five, admitted May 22, 1889. Had had pneumonia; base of both lungs dull anteriorly and posteriorly; no swelling, no râles.

May 23d.—Same condition as on previous day; no fever, no râles; base of both lungs dull, but not absolutely, as would be if there was water on the chest; no pleurisy, no bronchitis.

May 28th.—Examined. No fever; back of both lungs dull, dulness also extending in front; respiration not quickened; no râles, cough, or pleurisy. So:

*Diagnosis.*—Engorgement of lungs.

This case presented also a rare example, which I have recently seen repeated, of greatly diminished respiration, without quick breathing. Entered hospital with a diagnosis of "pneumonia of right lower lobe." If so, the pneumonia is well, and is followed by serous engorgement.

Case IV.—E. J——, admitted February 14, 1877, aged twenty-two. Had spitting of blood; no dulness under either clavicle, and anterior portions of both sides of chest resonant, respiration loud. Puerile respiration at back of left lung; percussion dulness over back of right lung, extending to diaphragm and liver, and absence of respiration; subcrepitant râles posteriorly.

*Diagnosis.*—Serous engorgement of right lung; spleen somewhat enlarged; respiration not quickened; pulse 120; temperature, 100° F. Ordered, ℞. Calomel, gr. ½; digitalis, gr. j.; ipecac, gr. ¼; squill, gr. ij. in each pill. One t.i.d.; chest to be rubbed with iodine and mercurial ointment (U. S. D.), and cod-liver oil and whiskey, on account of weakness.

February 25th.—Still weak. Subcrepitant râles very evident over right lung, with dulness—the serous engorgement involves whole of right lung. Dulness exists still at back of right lung also—not so marked as formerly, and crepitation on inspiration also diminished. Applied emplast. cantharides, 4 by 5, back of right lung.

Died April 3, 1877.

Case V.—P. B——, admitted 1888. Engorgement of lungs (or hypostatic congestion); had been in bed for three weeks on his back; no râles, partial dulness; all signs of hypostatic engorgement, viz., impaired respiration, posterior portion of lower lobe of lungs, mostly base and centre, dull.

Left hospital September 24th completely well. Took stimulants, milk diet, etc. In the above case "hypostatic congestion" and "engorgement of the lungs" are convertible terms.

Case VI.—P. M——, colored, aged sixty; admitted September 7, 1888, with a diagnosis of "chronic gastritis and malaria with anæmia."

September 8th.—Examined. Physical signs: Dulness on right side of chest, anteriorly, extending up to fifth intercostal space, and to about the seventh posteriorly; respiration in this region not good; left lung healthy; heart-sounds normal, but somewhat labored.

A tumor, about four inches in diameter and hard to the touch, found in the region of the stomach, just below the ensiform cartilage; no pulsations, but with considerable constriction of the abdominal walls just above the umbilicus—supposed cancer of stomach! Patient, about eight to ten hours after meals, vomits a considerable quantity of partially digested blood, or black vomit; pain considerable in the region of the tumor, which had been observed for one month past; patient anæmic. Dulness

and impaired respiration extend to the rear of the right lung; probably "engorgement of the lung."

Two cases may be added; one of "acute engorgement of the lungs," with recovery, and one, for comparison, an example of acute *congestion* of the lungs, with an autopsy.

CASE VII. *Acute Engorgement of the Lungs* (from notes, 1886).—D. G——, white, aged eight; suffered apparently from acute engorgement of the lungs, without crepitant râles; rusty-colored sputa, etc.; a "click" and dulness were present at the back of the right lung, middle region. Recovery took place after eight days' treatment. Temperature 101° to 102° F.; on the fifth day it was 103° F., even after using the following mixture: ℞. Sirup of squills, ipecac, and soda with nitre. This combination failed. Then the following: ℞. Calomel, gr. ¼; Dover's powder, gr. ½; soda, gr. j. Six powders, each containing the above. S.: One every three or four hours. Did not resolve the inflammation. Then local applications of mustard, followed by a thapsia plaster, with flaxseed tea as a drink. As fever became higher, employed, successively: ℞. Muriate of ammonia, 3 j.; carb. of ammonia, 3 j.; acetate of potash, 3 ij.; tinct. aconite, gtt. xx.; tinct. sanguinaria, 3 iij.; fluid extr. licorice, 3 ij.; water to ℥ iv. S.: Teaspoonful every two hours. Gave also a stimulating diaphoretic tea, made with senega and serpentaria, t.i.d.

Before the last mentioned was given, had used also, ineffectually, the following sedative and relaxant expectorant: ℞. Wine of antimony, 3 iij.; sirup. squills, sirup senega, āā, ℥ ss.; tinct. digitalis, 3 j.; sirup wild cherry bark, ℥ j.; tinct. lobelia, 3 iij.; water to ℥ iv. S.: Teaspoonful, t.i.d., and oftener if cough is troublesome.

He never had much expectoration, but his cough was troublesome, with constant fever; no pain; pulse, always 120, and respiration, 28. Under the aconite mixture, which is an excellent combination for pneumonic (?) engorgement, the temperature went down to 97° F. To-day, March 16th, sitting up; temperature, 98½° F. On the fifth day I used an oil-silk jacket over his flannel; the latter was wet with perspiration every night, and was changed.

It is instructive to compare a case like the above with our cases of "engorgement of the lungs." In the latter, which is not acute, there is no such high temperature. The absence of the crepitant râle, rusty-colored sputa, etc., in the above case, make its relations to pneumonia doubtful. Therefore I consider it a case of acute engorgement—not congestion, not pneumonia.

CASE VIII. *Congestion of Lungs; with an Autopsy* (from notes, December 5, 1880).—This case is introduced for comparison with cases of "engorgement of the lungs" and to show the acute nature and rapid invasion of congestion.

S. A.——, white, aged twenty-five, entered City Hospital, July 3, 1880, two days before death. Not very ill, apparently; said to have intermittent fever, and that on the previous night fever was very high. I could not ascertain that he had any congestive chills, or any prominent symptoms, after close inquiry from nurses and those lying near him.

When I saw him, July 4th, at 9 A.M., his respiration was slow and oppressed, and gradually becoming more so. He died in ten minutes after, though his pulse was not feeble—explained by the fact that death was caused by an apoplectic invasion of the lungs, while the heart was less involved.

*Autopsy*, July 5th. The cavities of the heart contained some blood; the pericardial sac held much bloody serum; much blood free in cavity of the thorax—a quart or more; both lungs hepatized or black with blood; *blood* was pouring from his nose at the autopsy (there had been white froth upon his lips at death, in striking contrast with his dark face). The spleen was soft and friable—not large, four by five inches; liver enlarged.

This man had not been severely purged (colliquative diarrhœa, whether natural or artificial, being, in my opinion, a frequent cause of congestive chills from diminished power of reaction which they give rise to). He must have died after brief sickness of *congestion* of the lungs—this being the most decided post-mortem confirmation of such a diagnosis I have ever seen. Have never seen so bloody a lungs and thorax; the structure of the heart also seemed softened and infiltrated with blood.

I cannot discover that this man had been purged before or after his admission. It is stated by the house physician that his fever had been very high the previous evening; no testimony showing the existence of any cold, chills, or excessive sweating. I regard diarrhœa, and *high temperature*, which liquefies the blood, as the dangerous symptoms. He had had ten grains or more of quinine, given him t.i.d. since his entrance into hospital.

## JABORANDI AND PILOCARPINE IN BRIGHT'S DISEASE.

BY P. R. EGAN,

ASSISTANT SURGEON, U.S.A., EAGLE PASS, TEX.

THE leaves of Pilocarpus pinnatus have been used to produce sudorific effects for centuries. The alkaloid has been before the profession for the last twelve years. Nevertheless, the truth of a recent statement will be readily admitted. Willoughby says (*The Lancet*, May 25, 1889): "There are few drugs of which the physiological action is so direct and palpable, but of which the therapeutic uses are so undetermined."

In the discussion which followed the reading of Dr. C. S. Wood's paper on "Some Points in the Treatment of Chronic Albuminuria, or Bright's Disease" (THE MEDICAL RECORD, March 24, 1888), pilocarpine was mentioned by but one speaker. Dr. Page's faith in the drug was not of a very exalted nature. "Pilocarpine," he added, "has been recommended for the purpose of eliminating this so-called uræmic poison. The chief objections to this remedy are its depressing effect upon the heart, and sometimes it causes such a profuse salivary secretion that the patient almost strangles." So, too, Heither, of Vienna: "He had never seen any good result follow the use of pilocarpine in renal disease after ascites had once set in. He admitted that it produced its physiological effects of increased perspiration and urination, but believed these to be purely temporary, and to have no beneficial result; whereas the depression consequent upon the use of the drug was not seldom alarming."

Before the New York Academy of Medicine (*Birmingham Review*) Dr. Francis Delafield brought forward a paper on the "Treatment of Acute and Subacute Nephritis" (THE MEDICAL RECORD, March 23, 1889). It was discussed by seven representative physicians of that great medical centre. But one referred to the use of pilocarpine—in truth, the remedy was almost ignored.

On the other hand, the general consensus of recent authorities on materia medica is that expressed by Stillé ("National Dispensatory"): "When dropsy arises in connection with desquamative tubular nephritis (especially scarlatinous), or even with interstitial nephritis, the medicine is very efficient; in the former case often leading to a cure, in the latter to a prolongation of life.

From Professor Wagner's clinic at Buda-Pesth comes the following: "When used according to the above-mentioned principles (*quod vide*), pilocarpine will be found in most cases of Bright's disease, even when hot baths and other diaphoretics prove useless, always to diminish dropsy to such an extent that the patient is more or less protected against dangerous uræmic suffocative attacks. In this way it may be possible to obtain a relative cure; that is, in secondary granular contracted kidney" (*British Medical Journal*).

In *The Lancet* for December 22, 1888, J. G. Marshall, B.A., M.B. Cantab., writes: "The value of jaborandi and its derivatives in the treatment of the dropsy of Bright's disease cannot be overestimated. By its use I have re-

lieved in several cases some of the most distressing features of this complication, and prolonged or rendered less painful the termination of life in others, but in none has the drug been exhibited with such satisfactory results as in the following case." Mr. Marshall then details the history of a fisherman, aged nineteen, who contracted Bright's disease, for which he was unsuccessfully treated at home and in hospital. When he again saw him "his face was livid, and the swollen condition of the cellular tissue of his neck made it almost as broad as his shoulders. He coughed incessantly; there was copious intra-thoracic effusion, and the subcutaneous tissue all over the chest was 'doughy' to the touch. His abdomen was as big as a barrel, and there was extensive œdema of the genitals. His legs and thighs were enormously swollen, and water was exuding from them. He was passing a small quantity of urine, which was of a dirty color and loaded with albumen." Mr. Marshall treated him with hypodermic injections of one-fourth of a grain of pilocarpine hydrochlorate. In a fortnight he was relieved of his dropsy, and passing his usual quantity of urine, which still contained some albumen. Mr. Marshall adds: "I think the almost miraculous improvement which followed the use of the pilocarpine is worthy of recording, and (when one considers the usual helplessness of a condition such as I have described in a patient of this age, and from such a cause) that jaborandi and its alkaloids must occupy the first place among therapeutic agents in the treatment of cases of this kind."

Although we may not agree with the statement of a recent authority that in puerperal eclampsia "nephritis is usually, if not always, present" (B. Holmes: *Medical News*, September 14, 1889), still it is sufficiently akin to acute and subacute Bright's disease to merit our consideration. Here, too, the same ambiguity prevails. The London Obstetrical Society cordially indorsed the opinion of Dr. John Phillips, that "although good effects were produced in twenty-eight cases, yet in nine such dangerous symptoms manifested themselves that he was bound to warn others against its use, especially when coma was pronounced" (*The Lancet*, October 13, 1888).

On the other hand, *The Lancet* for 1885 and 1886 contains an account by Dr. Horrocks, of Guy's Hospital, of two very severe cases treated successfully by the injection of one-third of a grain of pilocarpine, repeated to obtain its physiological effects. Cessation of convulsions almost immediately followed the use of the injection; the os rapidly dilated, and the children were quickly expelled, but did not survive. The maternal mortality is generally thirty per cent. A recent writer, however, gives twenty-three cases and no death (THE MEDICAL RECORD, September 7, 1889). *The Lancet* for 1886 also contains an account of five cases equally happily treated by Dr. Murphy, with similar injections of pilocarpine. One case so treated by him had thirty-three convulsions in the seventh month of pregnancy, but was afterward successfully delivered at term of a living child.

The writer desires to add two cases to the contribution of Mr. Marshall—one almost similar to his, but in which the result obtained by the use of jaborandi was better; the other a well-marked case of acute Bright's disease, with total loss of vision, which was restored in one hour and a half by the use of pilocarpine. Jaborandi and pilocarpine would seem to be especially indicated in all forms of Bright's disease. Its sudorific effect promptly eliminates the poison pent up in the system. Its well-known power of relaxing nervous tension in status epilepticus and kindred conditions (S. B. Lyon, *Journal of Nervous and Mental Diseases*, April, 1889; Willoughby, *ut supra*) is of the greatest service when eclampsia is threatened, or convulsions have already taken place. In a five years' experience (1882 to 1887) with jaborandi and pilocarpine in large doses, we have never seen, among non-debilitated subjects, any worse results than emesis, which at one time or another has attended almost every drug we have used. In Case I., instead of increasing the œdema of the lungs, as it is said to do, it relieved it after other remedies had failed.

CASE I.—J. R——, colored, aged twenty-four. Was seen on April 27, 1885, when he gave the following account of himself: About three months ago he began to swell in his legs and abdomen. Found that he could not easily button his "pants." Says he has never had any venereal disease, but has been a hard drinker. That two nights since, while camping in the valley, with insufficient covering, he suffered very much from cold. That he then began to cough, and rapidly to swell up.

Has anasarca of legs and body as high as his neck. His genitals and abdomen are very much swollen. A percussion wave cannot be obtained, but there is dulness on the flanks, changing with change of position. His heart is normal, but beats rapidly—120 per minute. Over his lungs are heard sibilant râles, and fine crepitation, but no dulness. He coughs almost constantly, and ejects mouthfuls of serous fluid. Says he has passed scarcely any urine during the last two days. A sample obtained is very dark colored, and became almost solid on heating. Under the microscope it was found to contain blood-corpuscles and granular casts. There were no nervous symptoms. Suffers from constipation. He was given pulvis purgans, acetate of potash in infusion of buchu and digitalis, and Stokes' mixture for cough. He passed about twenty ounces of urine each day, until May 1st. The albumen was slightly diminished, but otherwise there was no change. He was then given, morning and evening, ext. jaborandi, fl. ʒ j.; aq. menth. pip. ʒ j. Sig: To be taken at a dose; repeat in one hour if sweating is not produced. This dose produced its physiological effect without causing emesis. Pulvis purgans and Stokes' mixture also continued.

Next day there was a slight improvement.

On May 5th the following note was entered: Much better. Only few crepitant râles over lower part of chest. Œdema only noticeable over sternum. Passed thirty-four ounces of urine of light color; sp. gr., 1.015. No albumen or casts. On the following day it was noted—swelling gone from over chest. His recovery was uninterrupted. Ten days later he was given Basham's mixture alone, and in the first days of July he resumed his ordinary occupation. Seven months afterward, when last seen by me, he was found to be slim, wiry, and in excellent health. There had never been any return of his œdema, and albumen had not been detected after May 5th.

CASE II.—M. G——, aged twenty-eight. Was seen December 24, 1888. He had been suffering from sore throat for two days prior to seeking medical aid. Tonsils very much swollen and filling almost the entire pharynx. There is marked difficulty in swallowing, and some slight fever present. He was treated by ammoniated tincture of guaiac, aconite, and steam inhalations. On December 30th an abscess of the right tonsil was evacuated, all medicine discontinued, and a gargle of boric acid in hot water directed. He progressed favorably until January 10, 1889. On the morning of that date he complained of severe headache, and his face appeared swollen. This was thought to be due to a severe cold. During the forenoon he vomited twice—the vomited matters being bile-stained. About mid-day he fell into a sleep which lasted a couple of hours. At 3 P.M. he was assisted to the chamber, and then discovered that he was unable to see. He wanted to be told whether it was night or day. On my arrival I found him talking incoherently His legs and face were sufficiently swollen to leave a slight depression when firm pressure had been applied. His headache was very severe, and he was unable to distinguish daylight. A small quantity of urine obtained at the time gave a deposit equal to about two-thirds of its volume. He was given one drop of croton-oil in glycerine, but this was soon rejected. A rectal injection of one drachm of glycerine, repeated in twenty minutes, produced a slight watery evacuation. A hypodermic injection of one-sixth of a grain of pilocarpine hydrochlorate produced a free perspiration,

beginning ten minutes after its administration and lasting nearly an hour. In one hour and a half he could distinguish the faces of those around him, and at 7 P.M. he could distinguish a light about one hundred yards away. His urine under the microscope was found to contain granular tube-casts. The pilocarpine was again injected at 8 P.M. and produced a free perspiration.

January 11th.—Passed a small quantity of water twice during the night. Vomited twice. Swelling has gone from the face and almost wholly from the lower limbs. Can see everything about him, but distant objects seem misty. Passed twenty ounces of urine, containing about one-third albumen and some casts, during the last twenty-four hours. Was given one drop of croton-oil in glycerine, which acted freely. Pilocarpine injected night and morning. His recovery, from this point, was uneventful. He was given the pilocarpine night and morning until January 13th, when he passed thirty ounces of urine containing no albumen or casts, and having a specific gravity of 1.022. It was then injected once a day until January 15th, when he passed fifty ounces of normal urine. The swelling had all disappeared, and he expressed himself as feeling quite well. Seven months afterward I learned that he successfully passed the physical examination required for one of the government services.

*Remarks.*—From the symptoms, but more especially from the history of Case I., a diagnosis of chronic parenchymatous nephritis was arrived at. Mentally a fatal prognosis was registered. It appeared wholly similar to several acute exacerbations in chronic Bright's disease, observed while interne to a large hospital, and in which every remedy save jaborandi was known to have been unsuccessfully used. Imagine our surprise at the result of the treatment.

The Philadelphia *Medical News* for December 5, 1885, contains a *résumé* of a paper by Dr. Flint on "The Elements of Prognosis in Bright's Disease." (I am indebted to the kindness of Assistant Surgeon Ogden Rafferty, U.S.A., for copying and forwarding this article at my request.) He considered that, as a rule, acute and subacute Bright's disease does not tend to become chronic. That chronic Bright's disease may remain latent for a long time, which fact he considered of great importance. In view of these opinions the questions arose:

1. Can a case of subacute Bright's disease have a gradual onset lasting for three months?

2. Can a case of chronic Bright's disease remain latent for seven months?

To solve these interesting problems an attempt was made to learn the after-history of this patient, but unfortunately without success. However, relying on the well-known incompetency of the average member of the colored race to observe or define his symptoms, the case is deemed to have been one of subacute Bright's.

---

FAT IN THE FÆCES OF DYSPEPTIC CHILDREN.—Dr. Tschernow, of Moscow, has published his analyses of the fæces of dyspeptic infants, which he found to differ both physically and chemically from the fæces of healthy infants. Dyspeptic fæces contain eighty-five per cent. water and fifteen per cent. solids, and nitrogenous, fatty, and inorganic salts. The solids of normal fæces consist of from twenty-five to thirty per cent. fat, thirty to thirty-two per cent. albuminous matter, ten per cent. salts, and twenty-eight per cent. carbohydrates; while the solids of dyspeptic fæces contain forty-five to sixty per cent. fat, and fourteen to twenty-five per cent. albuminous matter. The carbohydrates do not differ very much. In dyspeptic fæces fat increases at the expense of albuminous matters. This proportion was observed alike in children at the breast and in those fed on artificial food. All dyspeptic fæces contain, as above mentioned, more fat than normal fæces, and the quantity of fat does not depend on the degree of indigestion. Dr. Tschernow concludes from these results that Demme's and Biedert's so-called "fatty diarrhœa" was simple dyspepsia.—*The Lancet.*

## LEGAL MATTERS OF INTEREST TO THE PHYSICIAN.

BY HENRY A. RILEY, ESQ.,

NEW YORK.

THERE are some accident policies which do not seem to insure against accidents. Here is one of them, as found in a New York case where the Preferred Mutual Accident Association was defendant. The policy stated that payments would be made to a member injured through "external, violent, and accidental means," provided said member shall "sustain bodily injuries by means as aforesaid which shall, independently of all other causes, immediately and wholly disable and prevent him from the prosecution of any and every kind of business pertaining to the occupation under which he receives membership." The insured was a retired gentleman having no occupation, who injured himself while operating a buzz-saw at the shop of a wagon manufacturing company of which he was a stockholder and director. As a result of the injury he was obliged to carry his arm in a sling, and was deprived of its use to some extent for several months. Under these circumstances the company refused to pay the policy, and in a lawsuit the court declared they need not pay it.

Two reasons were given for this adverse decision. The first was that the accident did not prevent his carrying on the business of a "retired gentleman," and the reasoning will make most retired gentlemen wish they were something else, provided their dependence is placed upon a recovery under an accident policy. The court said: "Can it be said that a man with his hand in a sling, and suffering a degree of discomfort from a painful wound in that member, is wholly disabled and prevented from the prosecution of every kind of business pertaining to the condition of a retired gentleman? The question is one which does not seem to admit of much discussion, but it would be easy to suggest many duties and even pleasures, pertaining to the domestic, social, and business relations of a retired gentleman, from which he would not be wholly debarred by a disabled hand. He might still, it would seem, keep an eye upon his investments, collect and disburse or reinvest his income, attend the meetings of the boards of directors of which he was a member, superintend repairs and improvements upon his property, and generally devote considerable attention to the care of himself, his family, and his estate." The "retired gentleman" must have, however, it appears, no accidents, for he cannot be protected against them, unless the disability is so entire that he could not even advise about his property. The second reason given by the court is that operating a buzz-saw is not the ordinary occupation of a "retired gentleman," and that if he voluntarily placed himself in such a position that he might come in contact with its rapidly revolving periphery, he had only himself to thank for any injury that might follow. He could not share his sufferings and sorrows with the insurance company. The policy, it seems, only permits a loss to the company when the injury is incurred in carrying on the ordinary occupation of a person. But as a "retired gentleman" has no very accurately defined occupation, it is difficult to see how there could ever be a loss which the company would pay. Possibly, if the "retired gentleman" were injured in some remarkable manner by the scissors with which he was cutting off his coupons, he might be able to recover; but if he were run over while passing along the streets he might be unable to get a cent, for how is it part of the occupation of a retired gentleman to be on the streets at all? Such refinements as these seem highly absurd, and if a person can get no protection from accident policies under like, or even somewhat different, circumstances, it would be well to let the accident companies alone.

How, indeed, can a railroad accident have anything to do with the occupation of a dry-goods clerk? Is not his occupation continually behind the counter, and what business has he ever to go on a railroad train? We wonder

how accident insurance companies can get business if they hedge themselves in from any possible loss by such conditions. The Indiana Supreme Court holds that shaving on Sunday is not a work of necessity, and is therefore illegal when performed for pecuniary compensation. This was the decision in Indiana fifty years ago, and the court holds that the reasoning and the conditions of life are the same now as then.

What constitutes necessity is well stated as follows: "The law contemplates that the community has a general need that all should rest on Sunday. Most of the affairs and doings of week-days are less important than this need of a rest-day, but some few are superior. To keep the body physically sustained by food; to provide the facilities for worship during some hours of the day, and for restful mental occupation during others; to nurse and heal the sick; to provide prompt burial for the dead; these and some other objects are superior to the need of general repose. Necessary work includes all that is indispensable to be done on Sunday in order to secure the attainment of whatever is more important to the community than its day of rest."

The law of nuisance has been invoked many times to prevent an exceeding variety of acts, sounds, or smells, and every little while some new word is added to the long catalogue of nuisances actual or alleged. Some which have occupied the attention of the courts are steam whistles, squealing of pigs, bleating of sheep, singing, ringing of bells, playing of pianos, hand-organs, and brass bands, tenpins, trundling of baby carriages, beating of drums, blowing of fifes, hammering of anvils, children at school, etc.

One of the latest cases, and one of the most curious, is found in the English courts, and the object was to prevent a gentleman who was suffering from softening of the brain, and who was a rather noisy invalid, from living next door to a boarding-house.

The court decided, however, that noisy invalids require attention and must have some place of shelter or home. It was said by the judge: "I have not been able to discover any precedent which is precisely applicable to the state of things presented by this case. Sick people must live somewhere, even if they make a noise. When we consider how the great majority of people in this country have to live, and in what houses, it would be absurd to hold that a man or woman who had a painful wound, and who screamed when it was dressed, or that a hysterical woman, or a person subject to fits during which he makes a noise, was only to live in an isolated house, or one the walls of which are of a certain thickness." There are some noises we must put up with, such as the playing of a neighbor's piano, or the noise of children in the nursery, and now it would seem that sick persons in a neighbor's house must be added to the list.

Physicians do more travelling in carriages than almost any class of persons, and they are therefore interested in many cases of damages for street runaways, and accidents occurring through excavations on the highway.

In a recent case in West Virginia, a horse driven by a physician fell into a hole near the travelled track of the street, and the question was whether the city of Huntington was liable in damages, the hole being unprotected and not marked.

The evidence was quite conflicting, but the vital part was contained in the physician's own testimony. He said "that he turned short in Third Avenue, and drove across the sidewalk for the purpose of hitching horse and buggy to the fence on a lot by the side of the house he was going to, which fence was outside the line of the street, and some thirty feet from the north line of the street, and he knew he was driving toward the fence." The court held that the point was whether Dr. Beardsley was in the street which the authorities were under obligation to protect, or had left it for his own convenience and without necessity. The jury in the first instance decided in favor of the doctor, but the appellate court reversed this decision and held that he must bear his own loss.

## THE PROPOSED NEW LUNACY LAW.

By FREDERICK PETERSON, M.D.,

FORMERLY FIRST ASSISTANT PHYSICIAN AT THE HUDSON RIVER STATE HOSPITAL FOR THE INSANE, POUGHKEEPSIE, N. Y.

THIS lunacy bill, drafted under the advice and direction of a committee of the National Conference of Charities, the chairman of which was Dr. Stephen Smith, ex-commissioner in lunacy of New York State, was introduced into the Legislature at Albany last winter by Mr. Gallup. It passed both the Assembly and the Senate, and would have become a law had not the Governor failed to affix his signature to it. As the same bill is to be reintroduced at the coming session, it is well that medical men in general should become acquainted with its more important features.

There is much to reform, much to improve, in existing lunacy laws, and most of the provisions of this bill are so excellent and admirable that it is to be hoped they will be favorably acted upon within the year.

The method of commitment of the insane to institutions contemplated by this bill is the only portion upon which there can be any discussion as to its advisability, and that point will be last considered in this article.

The really invaluable features of the new measure are, in brief, as follows:

*Removal to Asylum.*—It is provided that attendants of the same sex as the patient shall accompany the insane person to the institution. This applies more particularly, of course, to cases upon public charge. Under the present system, it has been my misfortune to see many a female patient brought to the asylum by one or more half-drunken deputized officials.

*Voluntary Patients.*—It is not uncommon for an insane person, cognizant of his mental condition, to desire to enter an asylum voluntarily. Under existing laws he cannot do so without recourse to the usual two medical certificates approved by a judge; and although easy to get in in this way, there may be difficulty in getting out. The new bill provides for the admission of such a case upon his written application, together with a corroborative certificate of his family physician; and he can leave the asylum at any time upon giving six days' written notice to the asylum superintendent, and two days' notice to the family physician who recommended his voluntary commitment.

*Emergency Cases.*—Patients requiring immediate care and protection can be received by institutions for three days without procedure of any kind by provision of the new bill. The evil that has resulted from the lack of such provision in our present laws is well known to asylum physicians and to those who have had to do with the commitment of suicidal, homicidal, violent, destructive, and nearly moribund cases, which, because of some trivial defect in the medical certificates, could not be legally received at asylums, and have been either returned to their homes or spent a night in a poor-house or jail until the flaws in the papers could be remedied.

*Confinement of the Insane in Jails.*—It is common in country-districts for a disturbed case to be placed temporarily in jail, often along with criminals, where he may, however, be detained for an indefinite period. The new bill forbids his confinement in the same room with criminals, and limits the detention to ten days at furthest.

*Home Furloughs for Asylum Cases.*—Under the existing law no provision has been made for patients who may be benefited by occasional visits at their homes during the period of their stay at the asylum. But in some institutions in the State, visits of ten days have been granted by the superintendents, on the ground that the medical certificates are legal for that period of time. I have known patients returning on the eleventh day, to be refused readmission without new certificates. The new measure arranges for furloughs of indefinite duration, according to the discretion of the superintendent of the asylum, the

commitment papers remaining in force during the whole of such leave of absence.

*The Boarding-out System.*—The boarding out of insane persons in private families at the expense of counties is permissible under the Gallup Bill, the superintendents of the poor to be fully satisfied of the good character of such families, and to visit the patients every three months. This applies more particularly to chronic cases taken from asylums, the superintendents of which must furnish a certificate as to the adaptability of the patients for care of this nature. This system is successfully practised in Scotland, some Continental countries, and in Massachusetts.

The above are the most important and valuable features of the Gallup Bill, and will appeal to everyone having at heart the welfare of the insane.

*Commitment to the Asylum.*—The manner of commitment contemplated in the new law is, in my opinion, positively harmful. The following is an outline of the method proposed:

When a person becomes insane, and it is necessary that he should go to an asylum, a justice of the peace, superintendent of the poor, or some judge of a court of record must be formally notified in this wise (Form B):

To Esquire, one of the Justices of the Peace of the Town of in the County of , State of .

SIR: Your informant respectfully represents that one residing at is insane and a fit subject for custody and treatment in a Hospital for the Insane, because ; and he therefore asks that the necessary steps be taken to investigate condition, as the law provides in such cases.

Whichever one of these officials has been notified then directs two physicians (in all probability political adherents, who will be thus rewarded for partisan services) to examine the alleged insane person, and report to him within one day, exclusive of Sunday, the result of the examination. The order issued to the physicians to make such investigation is as follows (Form C):

STATE OF , }
COUNTY. } OFFICE OF THE .

To , a legally qualified physician and Examiner in Lunacy, of County, State of .

Information in due form of law having been laid before me, alleging that one residing at is insane, and is a fit subject for custody and treatment in a hospital for the insane, you are hereby appointed to visit or see said person, and make a personal examination touching the truth of such allegations, and touching actual condition.

The physicians make each an exhaustive report according to a form provided for in the bill, too long to reproduce here, but to the thoroughness of which none can have objection, since the usually meagre details of our present certificates are as a rule decidedly unjust to the patient and useless to the asylum physicians about to undertake his treatment and care.

If the physicians report the patient not insane the case is dismissed; but if they find him insane and a proper subject for commitment, and make their report to a justice of the peace or to a superintendent of the poor, such official must himself also personally visit the patient and certify to the correctness of the proceedings and to his personal visitation, and must then deliver the medical certificates to a judge of a court of record within two days with the following certificate of his own (Form E):

To the Hon. , Judge of the Court, in the County of , State of .

SIR: I transmit herewith to you two medical certificates of insanity, in the case of , in the Town of in the County of , State of , made respectively by , M.D., and , M.D., Medical Examiners in Lunacy, qualified in accordance with the laws of this State, and acting under Commissions severally issued by me. I hereby certify to the correctness of these certificates and approve of their finding, which I have verified by a personal examination of said .

, Justice of the Peace.
, 18 .

Upon receipt of these three papers, the judge "may or may not visit the alleged insane person, or require that he be brought into court," but must state, in the order of commitment he then makes, whether he saw the patient or not, and if not, his reasons therefor. He may take further testimony or call a jury at his discretion. His order must read thus (Form F):

STATE OF , }
COUNTY. } OFFICE OF .

To the Superintendent of the for the Insane.

On the receipt of the certificates of two duly qualified examiners in lunacy, transmitted by , Esquire, one of the justices of the peace of the Town of in the County of , certifying to the insanity of of the Town of , and approved by the said justice, by whom said was personally visited and examined, I have seen and examined said respondent alleged to be insane, because it was not deemed necessary or advisable to do so, for the reason that ; and said respondent has been duly notified of proceedings taken in h case and of the time and place appointed for hearing, and had an opportuity to be heard thereon. The motion to take further testimony or to have a jury summoned was denied for the following reasons:

It appears to me, upon a full hearing and consideration, and upon evidence, statement, and certificates required by law, that said respondent is an insane person, and a proper subject for the treatment and custody of , a State insane asylum; and I so find. Therefore, it is ORDERED that *he* be committed to the , there to be detained until discharged according to law.

, Justice of the .

This order must be issued within five days after the last medical certificate. But before issuing this order, the judge is required to cause the alleged insane person to be fully informed of "the action about to be taken against him" (*against* him, forsooth, as if it were not *for* him, as if he were a malefactor instead of an invalid) and presumably such notification must be served personally upon the patient by a police officer deputized by the court.

In addition to the order to incarcerate the culprit in the psychopathic hospital, the judge issues a warrant either to the hospital superintendent or a proper county official to remove the offender to the institution he designates. If the warrant be issued to the former, he must send from the asylum attendants to convey the patient to the institution. When received, the medical officer of the hospital notifies the judge of the date of admission, persons attending the patient, etc., which paper the judge must cause to be filed with the commitment papers by the county clerk.

A brief summary of the steps in the complicated process may be presented thus:

1. A formal paper is made out by somebody (family physician?) notifying a public officer that a person is insane, and requires asylum care.

2. The official directs two physicians (very likely political on-hangers), in a formal paper to each, to examine the patient.

3. The two physicians make out two documents certifying to the insanity.

4. If said official be a justice of the peace or superintendent of the poor, he, too, must visit the patient, ascertain if the doctors were correct in their diagnosis, and, if so, approve of their finding and make out a formal paper

certifying to these facts. He then presents the three papers to a judge of a court of record.

5. The judge, if he does not care to bother about bringing the sick man into court, visiting him himself, or trying him by jury, merely makes out three more papers—one to be served upon the invalid, one an order committing him to some institution, and one a warrant for his transfer to the asylum.

6. Then the asylum officer gives formal notice to the judge of the receipt of the patient, and the judge must file this paper with the county clerk.

7. The judge must cause copies of the medical certificates to be filed in the office of the county clerk. He must also take proof as to the estate of the insane person, and file a certificate as to these facts with the clerk of the county.

Thus the papers requisite to the procedure are thirteen in number—one furnishing information of insanity; two notices to physicians; two medical certificates; two copies of the latter; one certificate from justice of the peace or poor-superintendent to judge; one notification to patient from judge; one order of commitment; one warrant for transfer to asylum; one notification of receipt of patient at the institution; one certificate as to patient's estate.

This may be slightly simplified by avoiding the justice of the peace and superintendent of the poor, and having a judge of the court of record first informed of the insanity, which will reduce the number of documents to twelve only, and, what is still more important, will dispense with one more annoyance to the sick man, viz., the personal visit of one of these officials.

To me the proposed law is somewhat confusing on one important point. I cannot quite clearly apprehend what becomes of the original medical certificates. The copies are to be filed with the county clerk. Nothing is said about the originals accompanying the patient to the asylum, which they surely ought to do; possibly their disposal has been forgotten in the multiplicity of details.

One's first query on looking over the Gallup Lunacy Bill would naturally be, "Is a sick man to be treated as if he were a criminal?" When his abdominal or thoracic viscera are acutely affected, and hospital treatment is required, he can be transferred without delay to the gentle ministry of a sick-ward; but when the most delicate organ of his body is diseased—his brain disordered—he must suffer visitation from two strange physicians, a public officer, and a policeman with a legal notification of his being a lunatic about to be taken to an asylum. It is unmerciful. It is pernicious. The law upon commitment is difficult enough of execution in its present form, and the truth is that the treatment of diseased brains in hospitals for the insane should, if anything, be rendered easier of attainment. Is an insane man an outlaw, to be thus treated, or rather maltreated? Rather make the access to asylums easy, and egress still more easy, and no harm will be done by wrongful detention! Rather throw open the general hospitals also to the curable insane, as they have recently done in far-away Victoria, Australia.

It is clearly to be seen that the framers of this law had in mind only the protection of a few cases, such as are often (generally unwisely) freed from asylums on writs of habeas corpus, and the prevention of the possible incarceration of a sane person in an asylum. But it is a narrow view to have this only in mind. To protect one doubtfully insane person, who is more than likely a troublesome paranoiac, nine hundred and ninety-nine are made to suffer.

That commitment upon the certificates of two physicians, sworn to, and approved by a judge, as now practised, is an efficient obstacle to the wrongful confinement of a sane person is attested by the fact that no sane person has ever been sent to an asylum in this State against his will. It is no argument to adduce the cases of "Nellie Bly" and other reporters, as has been done, who, for the aske of writing sensational newspaper articles, have sought entrance to institutions for the insane. Such persons would need but exercise a little more patience to run the gauntlet of all the provisions of the Gallup Lunacy Bill. I need but quote the following from a recently printed letter of Dr. John B. Chapin, who for many years was connected with asylums in this State:

"I have been familiar with admissions to four asylums for the insane during portions of thirty-four years that I have been connected with them, and I have never known of a single instance of the intentional commitment of a sane person as insane, nor of a single attempt to make such commitment; and I have no cases to report as coming within my personal knowledge."

And Dr. J. B. Andrews, superintendent of the State Asylum at Buffalo, formerly first assistant physician at Utica, writes:

"It has never been my misfortune to find in any case an effort on the part of medical men to declare a man insane and commit him to an asylum from any improper motive."

Here is the opinion of Dr. G. Alder Blumer, the present superintendent of the Utica Asylum, as to the adequacy of the law now in force:

"The present lunacy statute of New York State, if fully and conscientiously complied with, affords sufficient protection, in my judgment, against improper commitment."

Let the truly superior qualities of the Gallup Lunacy Bill, as above described, be amalgamated with the existing law as to commitment, and we shall have advanced a long step toward perfection in the elaboration of humane measures with regard to the insane.

201 West Fifty-fourth Street, New York.

### ANTIFEBRIN IN THE TREATMENT OF HEADACHES.

By HARVEY B. BASHORE,

WEST FAIRVIEW, PA.

About a year ago I began a study of the analgesic effects of antifebrin in the various headaches, and my treatment has been so gratifying that I wish to record it. In headaches of the nervous type, in facial and supra-orbital neuralgias—not very severe—I prescribe five grains every half-hour, and in severe cases I give ten grains, to be followed by a similar dose in three-quarters of an hour, if necessary; to be most effectual, the dose must be graduated according to the severity of the case and the peculiarities of the individual, and when this is accomplished the administration of the drug becomes very safe and its effects exceedingly reliable. Of five hundred or more cases of these affections which I have treated I have given relief to all but a few, and in most cases the entire disappearance of pain followed the administration of the remedy. But it is in sick headaches that antifebrin seems to me to be the best of all remedies, not even excepting antipyrin, which I have used with excellent success; antipyrin will do well enough in the prodromal stage, but in the later stages may cause gastric disturbances and provoke that distressing symptom rather than allay it; in simple migraine, antifebrin is, I think, the remedy indicated, and if given in the beginning will almost certainly abort an attack. I have treated fifty cases at least of pure migraine, and I know of no failure to ameliorate the symptoms when the drug was properly administered, and here, too, the dosage is important; in the prodromal stage of an ordinary attack, five grains every half-hour was generally sufficient—if the case was further advanced, large doses at longer intervals are better, such as ten or fifteen grains every hour for two or three doses. If there is much gastric disturbance the dose should be placed directly upon the tongue and very little liquid used in taking it; but it must be remembered that antifebrin will not so

much cure an attack as abort it, hence the necessity for the early administration of the drug. I may add that I have lately used phenacetin as an analgesic, but found it in no way superior to antifebrin.

In regard to acetanilid-poisoning, I have only noted it once in all my cases, and in that instance a much larger dose than prescribed was taken. From my year's work, then, and its results I conclude that antifebrin is

1. A most effectual analgesic for headache.
2. The remedy, par excellence, for sick headache.
3. And that, when used with the precautions necessary in the use of all drugs, it is absolutely without danger.

## SNAKE-BITE AND ALCOHOL.

By HOWARD H. HOPKINS, M.D.,

NEW MARKET, FREDERICK COUNTY, MD.

On August 16th I saw a colored child, four years of age, who, the day before, had been bitten three times on the leg, between the ankle and knee, by a copperhead snake (*Ancistrodon contortrix*).

The snake measured thirty-seven and a half inches.

Two of the wounds showed the imprint of but one fang; the other one showed the marks of both fangs.

The mother told me she had given the child, just after it had been bitten, about half a pint of *common* whiskey.

At the time of my visit the leg was much swollen and very painful; the effect of the whiskey was beginning to disappear, and, as the heart's action was good, I directed the application of cloths, wrung out in hot water, to the limb, but gave no medicine. In four days from the receipt of injury the child was running about as usual, and the swelling had almost entirely disappeared.

Being much interested in the effects produced by snake-bite, I made the inquiry, several years ago, among a number of the older physicians of this (Frederick) county, some of whom had been in active practice for over fifty years, and I could not find one who knew of, or had ever heard of, a well-authenticated case of death from snake-bite.

The only poisonous snakes in this section are the rattlesnake and copperhead.

Those cases of snake-bite occurring in my own practice have always responded promptly to *moderate* stimulation (alcohol or ammonia), and I am very much inclined to believe the *quantity* (to say nothing of the *quality*) of the whiskey generally given before medical aid arrives is frequently responsible for the alarming symptoms occasionally met with, rather than the venom, which, in this country at least, I believe is rarely injected in sufficient quantity to prove dangerous to life, unless it is received immediately into a vein.

I shall be under obligation to any of your numerous readers who will kindly furnish me with cases known to them where death has resulted from snake-bite.

## THE DANGER OF ANTIPYRIN.

A correspondent, H. B., writes: "I wish to report a case of antipyrin-poisoning that lately came under my observation, and enter a protest against its general and indiscriminate use by the public.

"The patient, Mrs. A——, had taken thirty grains of the drug, in three equal doses, six hours apart, for the relief of a facial neuralgia, as she had occasionally done before without any untoward effect. I found the patient half an hour after the third dose was exhibited (which, by the way, was taken at the soda-water counter in a druggist's) in a condition approaching coma. The train of symptoms that occurred in the ensuing hour seemed all out of proportion to the amount of the drug administered: temperature, 103° F.; vertigo, chill, marked convulsion, nausea and vomiting, and decided impairment of respiratory function. On cessation of these phenomena the patient complained of her eyes feeling like live coals burning in their sockets. The heart's action during this time was in no way disturbed. Ought not the sale of this drug to be prohibited, except by prescription?"

# Progress of Medical Science.

The Treatment of Eczema.—Dr. Unna says that, even before the experimental cultivation of bacilli, exact clinical observation had distinguished a number of entirely different types of eczema, and he thinks that each different type will be found to require a different mode of treatment. The type most frequently seen in Hamburg is seborrhœic eczema, and the parasite causing it is the same which in the first instance produces pityriasis capitis. Those persons who suffer from seborrhœic eczema of the head, including those affected with pityriasis capitis, are apt to suffer from the same kind of eczema on other parts of the skin. Dr. Unna has repeatedly pointed out that we possess a series of valuable remedies for the treatment of seborrhœic eczema in all its forms—viz., sulphur, resorcin, chrysarobin, and pyrogallol. Of these remedies resorcin is the best, as being the least likely to produce local or general ill effects. It may also be used in an alcoholic or watery solution, or in the form of ointment, paste, soap, or powder. Dr. Unna's favorite formula is a solution of three drachms of finely powdered resorcin, with an equal quantity of glycerine, in six ounces of spirits of wine, diluted with four times the quantity of water or camomile-tea. A thin layer of cotton-wool well moistened with the solution is applied, covered with some waterproof material, and fastened by a bandage. These applications are particularly useful when the treatment is prolonged, or when it is carried out by night. They are, of course, impossible in general eczema of adults, but not in that of infants. Dr. Unna describes an especially important effect following the application of resorcin—viz., a swelling of the epidermis, by which all painful fissures are healed in a single night. In order to insure healing, he advises that the skin should be anointed after the removal of the bandage, and that washing with soap should be avoided. A few people suffer from a resorcin idiosyncrasy which necessitates the immediate cessation of this treatment, and the application of powder to the affected parts. This idiosyncrasy is, however, very rare, as he has only met with it ten times in five years' observation, during which time he has seen two thousand cases. He remarks that his treatment is not adapted to those cases of long-existing eczema in which strongly infiltrated or thickly indurated patches occur.—*The Lancet.*

Dithio-salicylic Acid.—While working in the chemical laboratory of the Society of Physicists in Frankfort-on-the-Main, Herr H. Baum, chemist, recently discovered a substance which is likely to compete with salicylic acid as a remedy and antiseptic. This new substance, dithio-salicylic acid, consists, as it were, of two molecules of salicylic acid concatenated into one molecule by two atoms of sulphur (*The Lancet*). The well-known bacteriologist Professor Hueppe, of Wiesbaden, has ascertained that a twenty per cent. solution of sodium-dithio-salicylate kills anthrax spores in forty-five minutes, whereas sodium-salicylate under the same conditions has no perceptible effect. Its effect on cholera and typhus bacteria, on the bacterium of green pus, and on the staphylococcus aureus, is much stronger than that of sodium-salicylate. Sodium-dithio-salicylate II. (there is a similar substance called sodium-dithio-salicylate I.) has been tried in many cases of acute rheumatic fever in Dr. Knoblauch's wards in the city hospital of Frankfort. In the slighter cases a dose of three grains was given every morning and evening; in the severer ones the same dose every morning, and two, three, or four times an hour every evening. In slight cases pain, fever, and swellings disappear after two days; in severer ones, after six days at most. As

compared with sodium-salicylate, sodium-dithio-salicylate possesses the following advantages: Stronger effect and consequent adequacy of smaller doses, no bad effects on stomach, heart, and vessels, no collapse, no humming in the ears. A Frankfort physician had given a patient, who was suffering from acute rheumatic fever, six ounces of sodium-salicylate without any essential alleviation. He then tried the new remedy, giving the patient four doses of three grains daily, which cured him in five days.

THE GERMICIDAL ACTION OF BLOOD.—Drs. Nuttal and Buchner ("Ueber die bacterientödtende Wirkung des zellenfreien Blutserums," *Centralblatt für Bakteriologie und Parasitenkunde*) have added materially to our knowledge of the germicidal action of blood. Both defibrinated and freshly drawn blood manifest a decidedly deadly action upon bacteria, for more than four hours after it has been drawn from the body. This is most marked toward the pathogenic bacteria. For example, the number of anthrax bacilli in a given quantity of material was reduced in two hours from 4,800 to 56 by being mixed in a test-tube with defibrinated blood; and three hours later only three living bacilli remained. Almost as remarkable a germicidal influence was manifested toward other pathogenic bacteria. The destruction of putrefactive bacteria is, however, much less marked, and against some of them, at least, the blood manifested little germicidal influence. This is in accord with the latest ideas of the origin of parasitism. These investigations open up a new field of inquiry and thought, which promises a reorganization of our ideas of infection. We are brought back to consider the animal body a colony of individual cells, the integrity of which, when attacked by parasitic bacteria, depends upon the issue of the struggle for existence between individuals of the invading parasites and the individual cells of the body.—*The Journal of the American Medical Association.*

THE FIRST SOUND OF THE HEART.—Dr. Krehl, from investigations conducted in the Physiological Institute of Leipsic, has arrived at the conclusion that the contraction of the cardiac muscular fibres is the principal cause of the first sound, instead of being, as is now generally admitted, merely an accessory cause, or, as some will have it, entirely inoperative (*The Lancet*). The part played by each of these factors in the production of the sound can only be finally determined when the intensity of the full sound is ascertained, as well as the intensity of the several possible factors. But the difficulties of the case are well known; for while, on the one hand, the systole of the heart is found to consist of a single and sudden contraction, which it is held can produce no sound, since it produces only a single wave, and while it is rendered indistinct by the incompetency of the auriculo-ventricular valves, on the other hand, such experienced observers as Ludwig and Dogiel have satisfied themselves that under circumstances in which the sudden tension both of the auriculo-ventricular valves and of the vascular walls is impossible the first sound is still indubitably audible, from which it would appear that one, if not the chief, agent in its production is the muscular sound. The researches of Krehl were undertaken to test the truth of Ludwig and Dogiel's observations under conditions in which the play of the valves was still more stringently prevented, and this he believes he has accomplished by the employment of an ingeniously constructed little apparatus, consisting of a tube, from the extremity of which an expanding crown can be protruded, and by this means, when the instrument is introduced into the cavity of the heart, the valves can be firmly pressed back against the walls of the arteries. The animals used were dogs, and while after the insertion of the instrument one observer auscultated the heart, another alternately pressed in and withdrew the crown. The results obtained were that when the auscultator knew that the crown was thrust out and the valves compressed against the arterial walls, he perceived that the systolic sound was duller and a little less strong; but when with averted face he was unaware of the position of the crown, he was unable to distinguish any difference between the periods when the valves were acting and when they were not acting. This result obtained incidental confirmation by the fact that in all instances as the animals bled to death the second sound disappeared, while the first sound was still for some time distinctly audible; and additional evidence is to be found in the circumstance that, when in such cases the ventricle had ceased to contract and the auricle alone acted, a sound was clearly perceptible—that is, when the play of the valves had certainly ceased. He does not consider that he has been able to determine from his investigations whether the cardiac contraction is a simple convulsion or a tetanus, but he thinks that the sound may arise from the friction of the muscular fibres against each other; and this is supported by the observation or Dr. MacWilliam, that a sound is audible on simple convulsion or spasm of the voluntary muscles.

DIETETIC TREATMENT OF BRIGHT'S DISEASE.—The treatment of chronic renal affections by special forms of diet has recently been the subject of a series of investigations by Professor Schreiber, of Königsberg, whose results are of some interest in view of the present position of the question. He traverses Senator's statement that one ought in cases of albuminuria to forbid the use of eggs, holding that their injurious influence is open to question (*The Practitioner*). He took for the purposes of experiment eight people suffering from kidney disease, to whom he gave along with their ordinary diet six to ten eggs daily. Before the beginning of the experiment they had been under observation from four to eight days, on the usual diet, until the fluctuations in the amount of albumen in the twenty-four hours had been determined; the estimations being likewise made for several days after the eggs were discontinued. In four of the cases the eggs were administered boiled; in the others, raw. In the former group, the patients received six eggs daily, and in none of them during the period of administration of the nitrogenous food could any fluctuation or increase in the amount of albumen be determined. In the second group, six to ten raw eggs daily not only did not show an increase in the excretion of albumen, but actually led to a considerable diminution. Similar results have also recently been recorded from Leyden's wards. These observations also agree with those of Oertel, who has stated that the addition of a great quantity of albuminous food may affect albuminuria favorably. Schreiber maintains that none of the three forms of diet—mixed, meat, or milk—appears to be capable of influencing constantly and unmistakably the excretion of albumen in kidney disease—a result, he thinks, although really negative, to be nevertheless received with satisfaction when one considers that patients can never stand for any time a one-sided diet. In discussing the question how a patient suffering from Bright's disease ought to be dieted, Schreiber recommends that to an ordinary mixed diet should be added fluid or coagulated albumen, meat and other nitrogenous substances, and as there is not less albumen passed under a pure milk-diet than under a nitrogenous one, it succeeds better to combine the two and adds to the body-weight. A special diet for Bright's disease is not in the least indicated; it ought to be founded on the broadest basis, bearing in mind that the disease is an affection gradually and steadily consuming the bodily strength; while the forms of diet should be given according to the want and necessity, and without the unjustifiable and exclusive endeavor to compensate or change the loss of albumen by the urine.

---

DANGER IN SILK THREAD.—Silk thread is soaked in acetate of lead to increase its weight, and persons who pass it through the mouth in threading needles, and then biting it off with the teeth, have suffered from lead poisoning.—*Sanitary News.*

# THE MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PROPRIETORS AND PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

**New York, October 19, 1889.**

## THE DISEASED-MEAT SCARE.

THE *Nineteenth Century* recently published as its *pièce de résistance* an article on the diseases conveyed by butchers' meat. The author, Dr. Behrend, is unknown to us as a pathologist or sanitarian, but he seems to have collected industriously all the facts obtainable regarding tuberculosis of cattle and the dangers to human beings of infection therefrom. He quotes a statement recently made before the Berlin Medical Society to the effect that in some parts of Germany one-half the cattle are tuberculous; and adds that the only Continental town in which "a systematic inspection of all dead meat is enforced" is Hanover, where a careful examination of the various organs is made by experts who are continuously employed, and meat cannot be sold unless it bears a stamp affixed by them. In one month, at Hanover, 8,000 pounds of meat were condemned as tuberculous.

Eight thousand pounds means, however, only nine or ten cows. "But," says Dr. Behrend, "if we apply the Hanoverian standard, we shall find that 7,500 head of cattle thus affected are eaten by Londoners every year, and that, at the ordinary rate of computation, at least 375,000 of the inhabitants of the metropolis run the risk of being tainted with consumption."

Now all this is very interesting and important, and Dr. Behrend's article has excited much talk and learned editorial writing in the daily press. But it is yet entirely unproved that the meat of tuberculous cattle ever caused tuberculosis in man. Bovine tuberculosis is generally pulmonary. Tuberculous bacilli are found sometimes in the glands, but practically never in blood or muscle, except in acute general infection. Even if the bacilli do get in meat-muscle, Nocard, who is an ingenious and skilful bacteriologist, has shown that they are destroyed or digested in the tissue. And Nocard has positively affirmed that one can safely eat the flesh of tuberculous animals the tubercles of which are limited to the viscera and lymphatics. High temperatures destroy the bacillus also, and, therefore, thorough cooking would make even tuberculous tissue safe.

Dr. Behrend ought to know, also, that tuberculous meat can only infect the body through the alimentary tract; but Koch has shown that adult bacilli are destroyed in the stomach, and that the spore bacilli can only get through alive by a narrow margin.

But, furthermore, if tuberculous meat were so dangerous there should be more primary intestinal tuberculosis In adults this disease is a great rarity, and, practically, it may be ignored. Even including infants, it does not make up ten per cent. of tubercular diseases.

We venture to say, therefore, that the 375,000 Londoners who possibly ate the presumably tuberculous meat digested it and its bacillus, and were the better for their repast. It must be very evident, we think, that the danger to adults from eating flesh of tuberculous cattle is so extraordinarily remote that it may be practically ignored. The liver, "lights," and glands of such cattle, however, are perhaps not so safe, and sausage made up from meat seriously affected may not be free from danger. We advise, therefore, as we have done, the governmental inspection of slaughter-houses; but we much more seriously urge the supervision of milk. This, it is known, can carry the tuberculous virus, and, being consumed uncooked by delicate and growing children, is a far more dangerous product than the flesh of tuberculous cattle.

## THE CORONER SYSTEM.

EFFORTS are periodically made to abolish the coroner system in this and other States. These efforts have not been entirely futile, for they have caused the remedying of some abuses and have, perhaps, educated the people a little upon the question.

The last attempt to upset existing methods was made, we believe, by the Medico-Legal Society and Mr. Clark Bell in 1881. At that time the evils of the present coroner system, the political corruption, the gross stupidity and ignorance often shown in connection with its workings, were depicted, and our State Medical Society was asked to take some action in the matter. No material changes, however, were secured.

Lately the Society of Medical Jurisprudence has taken the subject up, and we learn that a committee has been appointed to investigate the matter.

The trouble heretofore has been that the State Constitution has stood in the way. This requires that each county appoint four coroners, and, with the powerful authority of this instrument to back them, adherents of the present system seem to have easily defeated attempts at reform.

It has been shown, however, that the Constitution, while calling for four coroners per county, does not explicitly lay down or limit their duties, and it is quite possible for the Legislature to arrange details so as to make their duties very slight and limited to other things than the examination of cases of sudden death. These latter duties, together with such others as are cognate, could be easily given by legislative action to medical examiners, as has been done now in Massachusetts for over ten years.

## THE DEADLY CURRENT.

THE death, within a short time, of three men by the electrical current has justly aroused a great deal of public excitement; and it is a grim commentary on the statements made not long ago regarding the uncertainty of electricity as a lethal agent.

In the indignation occasioned by the recent accidents, it is well to bear in mind that there are two sides to the question of electric-light currents, and that by carrying out measures for public safety too stringently an impor-

tant and useful industry may be crippled. It is possible that by careful insulation and underground wires even the thousand-volt currents may be made safe.

We should not forget that the railroads, and gas, and mines have a regular and large contingent of fatal accidents, which the public ignores unless inexcusable neglect and carelessness are shown. The same position should be taken as regards electric-light currents.

### THE FIRST PHYSIOLOGICAL CONGRESS.

The First International Congress of Physiology, which recently met at Basle, was attended by a number of eminent physiologists, and many interesting communications were made. These will after a time reach medical readers in detail; meanwhile, we would call attention to some of the more important topics that were discussed. Of course, Professor Goltz was present with his dogs and his theory of non-localization of the functions of the brain. This year Professor Goltz gave the history of a dog from which he had removed nearly the whole of the cerebral cortex. The dog lived fifty-one days, and though the animal had been rather stupid while in its anencephalic condition, it could still raise itself up and walk about. A dog was also shown in which nearly all the left half of the brain had been removed; yet it could walk, and use the muscles of the right side. All this, however, proves nothing against the clinical facts of cerebral localization, and it is time for the Antivivisection Society to protest against the further use of dogs, at least for futile experimentation.

Professor Heidenhain reported the results of a study of the formation of lymph, and claims to have proved that it, like glandular secretions, is the product of the activity of the cells of the capillaries. Heidenhain looks upon lymph as a fluid secreted for a purpose preliminary to the formation of urine. The lymph, he thinks, is a sort of reservoir in which are accumulated products to be used in urinary excretion. At the proper moment the lymph-products re-enter the blood, and are carried to and eliminated by the kidneys.

Educationists and sanitarians should be interested in an alleged discovery of Dr. Mosso, of Turin. By means of an instrument, called the ergograph, he is able, he says, to measure the condition of the brain by that of the muscles. His instrument serves to diagnosticate and dose the amount of mental work performed.

Professor Bowditch, of Boston, showed some composite photographs of doctors, car-drivers, and conductors. We are glad to learn that a distinct difference in the degree of intelligence is shown by the composites, but the reporter does not say in which class the highest form prevails.

Drs. Dastre and Loge, of Paris, have been making some experiments in order to determine what is the last reflex which persists in profound anæsthesia. This, it has been usually thought, was the oculo-palpebral, but Dastre and Loge say that it is the labio-mental. In other words, even after the oculo-palpebral reflex is gone, if one irritates the mucous border of the lower lip, there appear movements of the chin.

M. Minkowski described some experiments with dogs from which the pancreas was entirely removed; the result was a permanent diabetes.

A number of other communications of a somewhat more technical and purely scientific character were made at the Basle Congress. But it will be seen from the foregoing that physiological science is each year giving us new and fruitful advances.

### THE HYDERABAD COMMISSION ON THE ACTION OF CHLOROFORM.

There is still a doubt, in some scientific circles at least, as to whether chloroform first paralyzes the heart or the respiration. In Edinburgh, for example, we are told that failure of respiration is regarded as the chief or only danger in administering chloroform, while in London it is failure of the heart which is mostly feared. We have referred already to the experiments and experience of Surgeon-Major Laurie in Hyderabad, from which he has deduced very positive conclusions as to the innocuousness of chloroform so far as the heart is concerned. Some criticism having been made upon these views, his Highness the Nizam of Hyderabad has placed the sum of $5,000 at the disposal of *The Lancet*, for the purpose of paying the expenses of a commission to repeat the experiments and test the validity of the Scotch-Indian view of chloroform.

We are glad to learn that so distinguished a physiologist and pharmacologist as Dr. Lauder Brunton has consented to undertake the work, and has already sailed for India. The result of his trip will be watched for with much interest, though we doubt if anything can be found in India which will change the views which American surgeons have reached as the result of long experience.

## News of the Week.

Resolutions of Sympathy for Drs. Irwin, Ferguson, and Hance.—At the recent meeting of the Society of Medical Jurisprudence and State Medicine, a resolution was unanimously passed denouncing the unjust persecution of Drs. Irwin, Ferguson, and Hance in the Bishop autopsy matter, and expressing sympathy with and confidence in these gentlemen. This is as it should be, and is in perfect accord with the sentiment of the profession here and abroad. These gentlemen are beyond the suspicion of wrong-doing, the charges against them are absurd, and the proper thing for the prosecuting parties would be to exonerate the defendants promptly and effectually. Let us have an end to this uncalled-for and unjust persecution.

Compulsory Notification of Infectious Diseases.—The new Act of Parliament providing for the compulsory notification of infectious diseases comes into force at the end of next month. In London, the act is compulsory; in the provinces, its adoption is optional, and it rests with the local authorities to determine whether they will apply the act to their district or not. The bill was so "rushed" through the House of Commons at the last that no adequate discussion of the question of "dual notification" was possible. That system, therefore, remains an integral part of the bill, although it is one vigorously opposed by no inconsiderable section of the profession. In accordance with it, both the medical attendant and the patient's representatives are bound to notify to the medical officer of health for the district any case of infectious dis-

ease. A list of the infectious diseases to which the act will apply is given, but local authorities are empowered to make additions to the list at their discretion. Those named are the following: Small-pox, cholera, diphtheria, membranous croup, erysipelas, and the following fevers, viz., scarlet, typhus, typhoid, enteric, relapsing, continued, and puerperal.

ANOTHER CONFIDENCE MAN.—A smooth-spoken individual, of good address, and possessing a phenomenal familiarity with the "Medical Register," has been recently engaged in victimizing members of the profession in this city, representing himself as secretary of the "Commercial Travellers' Association." On the strength of his references (such as cards from reputable physicians) he seeks to interest doctors in a scheme for giving medical assistance to commercial travellers, stating that he has been commissioned to engage physicians in each town and city in the State to attend sick drummers and their families. The credulous victim is induced to advance a few dollars to purchase blank forms.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.—The next annual meeting will be held in Albany, February 4 to 6, 1890. The Business Committee has been appointed as follows: Dr. George H. Fox, 18 East Thirty-first Street, New York; Dr. Henry Flood, Elmira; Dr. Herman Bendell, Albany. Application should be made before January 1st by those desiring to read papers, in order to secure the proper arrangement of time and subjects. Papers should not exceed fifteen minutes, and the title should accompany the application, which may be made to any member of the committee.—DANIEL LEWIS, President, 62 Park Avenue, New York.

THE AMERICAN PUBLIC HEALTH ASSOCIATION meets in Brooklyn next week, and New York physicians have been asked to help in entertaining the guests. We trust that the profession in this city will generously respond.

MASSAGE OF THE HEART, which is Dertel's latest device in mechano-therapy, consists essentially in causing the patient to make slow, forced expirations, while the masseur, with his hands upon the ribs, assists the expiratory effort, pressing the hands forward toward the ensiform cartilage. The patient then takes a deep inspiration. The process increases the strength of the heart's systole and helps the diastole.

THE DIGITALIS OF THE LUNGS is a name fancifully given to quebracho by Dr. E. M. Hale (*N. A. Practitioner*). This is a drug which has failed to hold its place in therapeutics, though occasionally it seems useful. Dr. Hale says that the alkaloid aspidospermine, in doses of gr. $\frac{1}{100}$ to $\frac{1}{500}$, has a better action.

A NEW COLLEGE OF PHARMACY.—The Kings County Pharmaceutical Society has had under consideration plans for the establishment of a college of pharmacy in Brooklyn. It is reported that the preliminaries have all been agreed upon, and that before many months a fully equipped school will have been launched.—*N. Y. Medical Journal.*

SCARLET FEVER IN LONDON is still on the increase, and it is thought that another of the hospitals of the Metropolitan Asylums Board will shortly have to be opened.

A POST-GRADUATE COURSE FOR LONDON is projected, to commence in January next. Several so-called "post-graduate" courses have already been held in London, but in every one of those hitherto held the venture has been in connection with one particular hospital, to which the instruction given has been confined. The new scheme is for a course comprising clinical teaching at several hospitals, which have arranged for joint action in the matter. The first course is to be given by members of the staffs of the following hospitals: The Brompton Consumption Hospital, the Hospital for Sick Children (Great Ormond Street), the National Hospital for the Paralyzed and Epileptic, the Royal London Ophthalmic Hospital, and the Hospital for Diseases of the Skin (Blackfriars). It will be noted that these are all special hospitals without medical schools (though all are at present available for clinical study), and this marks a new departure, for all the "post-graduate" courses hitherto given in London have been in connection with one of the general hospitals to which medical schools are attached. Should the new scheme succeed, it will doubtless be largely extended by arranging for other hospitals to join it. Otology and gynecology will then probably receive attention also. It is somewhat remarkable that a course omitting them should have been announced. Three courses a year are to be given. These will commence in January, May, and October, respectively, and each occupy eight weeks. The duration of the courses is, perhaps, the weakest part of the scheme. A fee of ten guineas will be charged, or three guineas for the demonstrations at any one hospital.

A CONTEST has been going on in Brooklyn between Dr. George R. Fowler and Dr. Nelson B. Sizer as to who should be head of the medical staff of the Bushwick and East Brooklyn Dispensary. It is asserted by Dr. Fowler that Dr. Sizer was elected president at a packed meeting. The matter has been brought before the courts.

DR. THOMAS SNOWDEN, one of the leading physicians of Peekskill, N. Y., died in this city on October 11th. Dr. Snowden came to this city on October 3d to arrange for the admission of his son to college. He was suddenly struck down by apoplexy. Dr. Snowden graduated from the College of Physicians and Surgeons in 1849.

THE DIAGNOSIS OF EXTRA-UTERINE PREGNANCY.—Dr. J. M. Baldy, of Philadelphia, writes: "In my article on 'The Early Diagnosis of Extra-uterine Pregnancy,' in THE RECORD of September 21st, I made the statement: 'Also of Janvrin, who stated at the Washington meeting of the American Gynecological Society that the diagnosis of extra-uterine pregnancy was easier than that of normal pregnancy.' Dr. Janvrin writes me that he never made such a statement, or anything that could be so interpreted. I had thought I had heard him make the statement myself, but of course must have been mistaken. I wish, therefore, to withdraw the quotation."

THE AMERICAN ACADEMY OF MEDICINE is endeavoring to make as complete a list as possible of the Alumni of Literary Colleges, in the United States and Canada, who have received the degree of M.D. All recipients of both degrees, literary and medical, are requested to forward their names, at once, to Dr. R. J. Dunglison, Secretary, 814 North Sixteenth Street, Philadelphia, Pa.

NEW YORK STATE MEDICAL ASSOCIATION, OFFICERS ELECT.—The following were elected on the last day of the session of the Association: *President*—John G. Orton, of Broome County; *Vice-Presidents*—Douglas Ayres, of Montgomery County; W. H. Burton, of Rensselaer County; E. Mott Moore, Jr., of Monroe County, and William B. Eager, of Orange County; *Secretary*—Everard D. Ferguson, of Rensselaer County; *Director of Library*—John W. S. Gouley; *Members of the Council*—First District—C. M. Klock and W. H. Biggam, of Montgomery County. Second District—Thomas Wilson, of Columbia County. Third District—H. O. Jewett, of Cortland County. Fourth District—Simeon T. Clark, of Niagara County. Fifth District—John G. Truax, of New York County.

THE "MEDICAL WAIF" has been wafted into the embraces of the *North American Practitioner*, which esteemed journal has absorbed and extinguished it.

"DIPHTHERITIC SORE THROAT."—The editor of the *Indiana Medical Journal* truly and forcibly says, regarding the above expression: "There is no such disease known to medical science. An individual either has or has not diphtheria. If the former is the opinion of the physician, let him say so; if the diagnosis is uncertain, it is also best to say that or nothing. Surely there is no excuse for the use, under such circumstances, of terms which are both professionally and popularly misleading, and which imply a belief that there is a condition which has a diphtheritic element and yet is not diphtheria."

A TRAINING SCHOOL FOR NURSES has been opened in connection with Johns Hopkins Hospital.

MANHATTAN EYE AND EAR HOSPITAL.—Dr. W. M. Leszynsky has resigned from the Manhattan Eye and Ear Hospital.

SOME OF OUR ESTEEMED Chicago contemporaries are worrying over the meagre show which the medical profession can make at a World's Fair. "What," says the *N. A. Practitioner*, "have we got to show the medical men of the world?" We think that our contemporaries and colleagues are feeling unnecessarily disturbed.

A NEW SOURCE OF MORPHINE.—MM. Adrian and Bardet, after investigating the properties of the California plant *Eschscholtzia Californica*, say that it contains an alkaloid identical with morphine. The *Occidental Medical Times* publishes an account of the plant written by Dr. W. P. Gibbons. It is therein stated that the plant belongs to the *Papaveraceæ*. Years ago he made some experiments with it, but got no definite results.

THE GREAT COMPOSER.—Being asked the name of the world's greatest composer, a smart university young man said: "Chloroform."—*Philadelphia Record.*

DOCTOR—"Not so well to-day, eh? Have you kept him quiet and given him his medicine regularly?" Mrs. Richard Bevylin Buckner—"Dey 'ain't been nobody in de room wid him 'cept me an' de children, so he's been nice an' quiet; an' I give him de med'cine like you tole me—three spoonfuls every hour." Doctor—"Great heavens, woman, it's a wonder he's alive! I said one spoonful every three hours." Mrs. Buckner—"Well, now, Doctah, dey ain't no diff'rence between one three an' three ones. Count 'em fo' yo'self an' see."—*Harper's Bazar.*

## Reviews and Notices of Books.

A MANUAL OF DISEASES OF THE EAR, FOR THE USE OF STUDENTS AND PRACTITIONERS OF MEDICINE. By ALBERT H. BUCK, M.D. Pp. 420. New York: William Wood & Co. 1889.

THE present volume is more or less a revised edition of Dr. Buck's previous work, entitled "Diagnosis and Treatment of Ear Diseases" (1880), and is, as the title states, especially intended for students and practitioners of medicine. This book is, however, a more systematic and scientific essay than the author's former volume.

Among the more especially revised portions of the work may be mentioned the treatment of different forms of acute and catarrhal inflammation of the middle ear. Here considerable space has been devoted to the importance and manner of removal of adenoid vegetation from the vault of the pharnyx, and to the application of other local remedies to the naso-pharyngeal mucous membrane. Chapter XII., dedicated to diseases of the mastoid process, is a very comprehensive sketch of the subject, and well supplied with excellent illustrations. The writer goes very elaborately into the treatment with the drill, chisel, etc., of which procedure he is a well-known advocate. Chapter XIV., on syphilitic and tubercular disease of the deeper parts of the ear, will be found interesting reading. In the appendix is given a short and concise anatomical and physiological sketch of the ear, with numerous well-selected illustrations. The index is unusually complete.

DISEASES AND INJURIES OF THE EAR: THEIR PREVENTION AND CURE. By CHARLES HENRY BURNETT, A.M., M.D. Pp. 154. Philadelphia: J. B. Lippincott Company. 1889.

DR. BURNETT'S little book forms one of a series entitled "Practical Lessons in Nursing," the contributions of several different authors, and published by the above-named firm. The writer presents to the public a very readable little work, and which, owing to the absence of technical terms, will be easily understood by most persons. The object of the author has been to show the public how ear diseases may be avoided by care, and, in case they have contracted affections of the hearing organ, to warn them against the numerous experimental forms of treatment so much in vogue and so often disastrous. Dr. Burnett has certainly carried out his idea in a very successful manner. Especially good is the advice he gives in relation to foreign bodies in the external auditory canal, where meddlesome treatment so frequently results in disaster. Equally valuable are his remarks about the effect of diseased teeth, dental plates, and fillings, in the causation and maintenance of aural troubles. The author goes quite fully into a detailed description of the causative influences in chronic catarrh of the middle ear, and gives many valuable hints and suggestions from an hygienic point of view. The book contains a few illustrations of the anatomy of the ear, sufficient for explanatory purposes, and an excellent index.

TRAVAUX D'OBSTÉTRIQUE DU DR. A. ANVARD. Tomes I.-III. Paris: Lecrosnier et Babé. 1889.

OBSTETRICAL WORKS OF DR. ANVARD. Three volumes. Paris.

IN these rather bulky volumes Dr. Anvard has embodied most of the doctrines and methods of practice now current in the department of obstetrics in France. With some unimportant exceptions, those doctrines agree with what is taught in our own country. Antiseptic accouchements, or rather aseptic ones, are the aim and object of French obstetricians, as well as those of other civilized countries.

# Society Reports.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, October 3, 1889.*

THE PRESIDENT, ALFRED L. LOOMIS, M.D., IN THE CHAIR.

DR. C. L. DANA read a paper entitled

### THE PATHOLOGICAL ANATOMY OF CHOREA—A CASE, WITH AUTOPSY.

It dealt chiefly with the pathological anatomy of the nervous centres. Those occurring elsewhere, particularly in the heart, had often been described. There was pretty definite agreement that the most uniform condition in cases dying with chorea was fibrinous deposits on the valves of the heart, usually the mitral. It occurred in ninety per cent. of the cases. Turning to the nervous side, he first gave his own case. The patient was a Swiss, aged eighteen, single, whose family history was unknown. He was admitted to the hospital, December 15, 1888. He had always been weak and sickly as a child; no rheumatic, venereal, nor alcoholic history. He began to have choreic movements twelve years ago, or at the age of six years; cause unknown. The movements at first were not severe. He had had so-called epileptic attacks at occasional intervals for several years. Formerly they occurred at night only; later they came on during the day also. They began with a shrill cry.

### PHYSICAL EXAMINATION AT THE HOSPITAL.

The patient lay abed, unable to walk or help himself because of the violence of the choreic movements. He was dull, but answered questions intelligently. Speech slow and jerky. There was the mark of a former trephining for epilepsy. There was no paralysis, no heart murmurs; lungs and abdominal viscera normal; urinary examination negative. The movements were so severe that he could not feed nor help himself. He had several epileptoid attacks daily and nightly. The fits were of a hysteroid character, seemingly not strictly epileptic. Dr. Dana had not himself seen an attack.

The patient improved considerably under chloral hydrate and other treatment until January, 1889, when he contracted pneumonia and died. The autopsy showed the lesions of pneumonia. The heart was normal, and showed no vegetations on the valves. The skull was unusually thick, seven-eighths of an inch on section through the occipital bone. The pia mater was thickened, not markedly adherent; the cortex of the brain appeared normal to the eye except for very superficial softening on the under-surface of both temporal lobes. The cord was apparently normal. Sections were made of the brain, cord, and several of the nerves for microscopical examination.

Two or three cuts were made vertically through the brain when it was fresh, and appeared to be slightly congested, but there appeared to be no spots of softening and no hemorrhages. However, the deeper parts of the brain did not harden well for microscopical study. Under the microscope pieces were examined from the motor, temporal, and biparietal convolutions, corpora striata and thalamus, bulb and cord, and some of the nerves. There was a slight amount of lepto-meningitis, the gray matter was considerably injected, the neuroglia was not markedly increased, occasionally a cell was seen undergoing pigmentary degeneration. The nerve-fibres could be seen running up into the cortex, and the transverse fibres of the cortex were also present. The chief changes were just beneath the cortex where the white matter was honeycombed, the change in some places being apparent even to the unaided eye. The walls of the blood-vessels were somewhat thickened, but not markedly so. There was no real arteritis or endarteritis, but the vessels had been much distended by exudates of blood-cells, with dilatation of the perivascular spaces. The process, though chronic, could not be looked upon as inflammatory. It was due rather to flabbiness and loss of tone of the vessel-walls. There were no colloid bodies. At the base and tip of the temporal lobe, however, there was softening, a severer grade of meningeal inflammation, the white matter beneath was more excessively honey-combed, while there was evidently an increase of the neuroglia-cells. The basilar ganglia and internal capsule did not appear to the unaided eye so much involved as did the subcortical tissue, although some portions of the internal capsule, the deeper parts particularly, did not harden well and sections could not be made. The optic thalamus and anterior part of the caudate nucleus showed the same honey-combed appearance from vascular dilatations, though less marked than in sections higher up. The lenticular capsule showed more serious degenerations, the walls of the blood-vessels were even degenerated and seemed to fall to pieces, and some of the nerve-fibres seemed swollen and disorganized, although some of these changes may have been post mortem. The nucleus of the fourth cranial nerve seemed degenerated.

The spinal cord showed some congestion; the distended and thickened vessels were most numerous, apparently, in the lateral columns. It had none of the honey-combed appearance found in the brain and pons. In the lumbar cord a double canal was present, and for a short distance one could see three canals, apparently, with epithelial lining. The anterior and posterior roots showed no degenerated fibres. Macroscopically, the cerebellum seemed normal.

The severest changes existed under the surface of the temporal lobes, in the internal capsule, in adjacent parts of the corpora striata; the pons Varolii and medulla showed the same condition, much less marked. There was slight connective-tissue increase in the pyramidal tracts, the spinal cord showed slight lepto-meningitis and congestion in the lateral tracts, a double canal in the lumbar region.

The author then reviewed cases reported by other writers. The mortality from chorea, he said, seemed to be much greater in England than anywhere else. In the English hospitals three or four per cent. of all the cases ended fatally. He knew of only three fatal cases in America, reported in detail. He had examined and tabulated the post-mortem records in over eighty cases. Eliminating the duplicated ones, he had found on record nearly two hundred reports of autopsies. The large majority were of no value as indicating the nervous lesions. Indeed, he had found only thirty-nine cases in which a satisfactory account had been given of the nervous system, and even here, in some instances, the examination had not been complete.

They had shown congestions, extravasations, emboli, and softening in the nervous centres; they had also proven the great uniformity of heart-lesions. It was, however, only by very minute and critical microscopical examination that light had come. But the records of the complicated, of the uncomplicated, of the acute, and of the chronic cases should be studied separately. It was only the acute and chronic chorea of the Sydenham type which one ordinarily met, and it was this disorder in which the pathological anatomy should be especially studied.

Among the thirty-nine cases with autopsies of the nervous system, there were twenty-five in which the disease was the acute chorea of Sydenham, uncomplicated with other serious disorders. Leaving out six cases, for special reasons, there remained nineteen in which a careful microscopical examination had been made. In sixteen there was a record of intense cerebral hyperæmia, periarterial exudations, spots of softening, and minute hemorrhages, and, occasionally, aneurisms. Of the remaining three cases, in one absolutely no changes were recorded, but Dr. Dana thought some must have been overlooked.

In five chronic cases, lasting from four to twelve years, there were found dilatation and thickening of the arteri-

oles, with necrotic changes, spots of sclerosis, fungus growths along the vessels in one case. The cord was somewhat similarly involved, though less in extent.

Dr. Dana thought we were not far from obtaining an anatomical basis for chorea. In the acute types there was hyperæmia of the brain, and of parts of the cord. In the brain it was not meningeal, but affected the deeper parts; it was more than an ordinary congestion. The arterial walls were paralyzed, dilated, badly nourished, and an exudation took place. Sometimes there were thromboses and spots of softening, or the vascular walls gave way and some small hemorrhages took place. On the other hand, the lymph-spaces around the nucleated cells and neuroglia were not dilated; no proliferation of connective-tissue cells, no distinct sign of inflammation. The process was one of vaso-motor paralysis. "Inflammatory," or "subinflammatory," was not strictly a correct term to apply to it. In the older cases the vascular changes were more marked, the small arteries were permanently dilated, a little thickened, varicose, and the other peculiar changes which had been described took place.

Admitting that there were the vascular and degenerative changes already indicated, we had yet to learn the cause before we could know the pathology of chorea. Several theories had been advanced, as the humoral, the embolic, the subinflammatory, the functional or agnostic, and the infectious theories. After briefly considering these, the author said there were three things at least which had been well determined in chorea, namely, the existence of an abnormal state of the blood, an intense cerebral hyperæmia in certain parts, and a neurotic history. He asked if we must not logically combine a humoral and a neurotic theory to explain chorea. The disease was a kind of traumatic neurosis occurring in children with impoverished blood. Repeating, he said that in chorea there was a neuropathic and a humoral state, the preponderance of the two varying in different cases, and giving indications for treatment.

Dr. L. C. Gray being asked to open the discussion, thought little remained to be said except to congratulate the author on his excellent and exhaustive treatment of the subject.

Dr. M. Allen Starr made some remarks on the theories of the causation of chorea, and said he had inclined toward the infectious theory, although it had not been proven, and there were some objections to accepting it, at least in all cases. As Dr. Dana had said, three cases had been recorded in which a micro-organism had been found, and he therefore thought all cases should be studied in this regard. Rheumatism and heart complications favored the infectious theory.

It might be questioned, he thought, whether, in the cases of chorea which lived, the pathology was exactly the same as that in the cases which died. Nerve-cells had the power of discharging their energy, and consequently of causing spasmodic manifestations under a great variety of conditions; it was not necessary that the cell be irritated by a micro-organism, or an irritant in the blood. It was noticeable sometimes after fatigue and exhaustion; he therefore believed that some cases of chorea must still be regarded as functional, and that we could not lay down for all cases a definite pathology such as was found in cases that died.

Dr. M. Putnam-Jacobi cited two cases published in the last issue of *Brain*, in which the pathological changes had been described, and said it seemed scarcely possible that the ubiquitous bacteria should lie in wait just at the time when the child fell down the cellar, or experienced a strong emotion, which was immediately followed by chorea. Dr. Dana's case seemed to imply a congenital defect in the nerve-centres, indicated by the three canals in the lumbar cord.

Dr. W. R. Birdsall admitted the importance of the pathological findings described by Dr. Dana, but he thought it equally important to give the proper interpretation of those findings. It might be a question whether the chorea had been caused by the lesions, or whether the lesions had not been caused by deranged action in the nerve-centres attending chorea. With functional disturbance in the beginning sufficient to cause convulsive action, it was but natural that vaso-motor paresis should follow, and, in time, more decided vascular changes. He thought a variety of conditions might produce disturbances of a choreic character, and finally lead to the pathological changes described.

He also mentioned a family in which several of the members developed chorea, and the cardiac and exophthalmic symptoms of goitre.

The President made some remarks on the very common presence of chorea, rheumatism, and cardiac symptoms in the same subject, and was disposed to think with Dr. Birdsall that the lesions described by Dr. Dana were to be found in other nervous diseases of a functional nature of considerable duration, although the location of the lesions might not closely correspond.

Dr. Dana closed the discussion, and said he knew of no other disease in which the same pathological changes had been found as in chorea.

## AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

*Second Annual Session, held at the Burnet House, Cincinnati, O., September 17, 18, and 19, 1889.*

William H. Taylor, M.D., President, in the Chair.

After an address of welcome, by Dr. Comegys, of Cincinnati, the following papers were read: "Congenital Sinus of the Urachus: Abdominal Incision, Recovery," with remarks, by Dr. A. Vander Veer, of Albany, N. Y.; "A Case of Extra-uterine Pregnancy: Operation and Recovery," by Dr. L. S. McMurtry, of Danville, Ky.; "Intra-uterine Cord Amputations of the Fœtal Extremities," by Dr. Joseph Price, of Philadelphia, Pa.; "Flap-splitting in Perineorrhaphy, with Special Reference to Tait's Operation," by Dr. X. O. Werder, of Pittsburg, Pa.; "Vaginal Hysterectomy," by Dr. E. E. Montgomery, of Philadelphia, Pa.; "Supra-vaginal Hysterectomy: Extra-peritoneal Dry Treatment of the Pedicle," by Dr. Joseph Price, of Philadelphia, Pa.; "Successful Removal of a Fibrous Tumor of the Right Ovary during Pregnancy," by Dr. J. H. Carstens, of Detroit, Mich.; "A Remarkable Case of Nymphomania," by Dr. W. S. Stewart, of Philadelphia, Pa.; "A Few Considerations on Peritoneal Effusions after Intra-peritoneal Operations," by Dr. W. H. Meyers, of Fort Wayne, Ind.; The President's Annual Address; "Reasons for Drainage in Ovariotomy," by Dr. Hampton E. Hill, of Saco, Me.

On the afternoon of the third and last day the session was given up to the discussion of the subject,

### Is craniotomy justifiable on the living child? and its alternatives.

Listerism received some hard knocks, as did also electricity in gynecology. One gentleman who was especially severe, and a good deal more positive than our science will allow, said electricity was used only by the ignorant, and those who had never been in the abdomen. He cited as a specimen a doctor in his city who was a great advocate of electricity, and he scarcely knew whether the pubis or the sacrum was before. This same speaker, after having vented his venom on Listerism and electricity, turned to compliment a fellow who had agreed with him in his paper, and said he described a case as perfectly as *Mozart* could have *painted* it. If his ignorance of Listerism and electricity was as profound as his familiarity with music and painting, it is not to be wondered that he avoids them. Another antagonist of electricity made a boast that he had not a battery in his office. Drainage was discussed freely, and as a general thing warmly endorsed. One gentleman, Dr. Hill, reported twenty-six ovariotomies in which he used the drainage-tube twenty-four times and had twenty-

five recoveries. He made twelve ovariotomies without losing a case before he ever saw the operation done. His work was highly praised by the members. Flap-splitting in perineorrhaphy was severely condemned. Abdominal surgery was lauded to the skies, and should be limited to the hands of the specialist.

Socially the Association was very kindly entertained. The city of Cincinnati was thrown open to them. Dr. and Mrs. Taylor gave a reception, to which the Association was invited to meet the local profession. This was a very enjoyable occasion, and the Cincinnati doctors made themselves as agreeable as possible. The local members took the Association to see "Montezuma, or the Conquest of Mexico," which was also very much appreciated.

The election of officers resulted as follows: *President*—Dr. E. E. Montgomery, of Philadelphia; *First Vice-President*—Dr. W. H. Meyers, of Fort Wayne, Ind.; *Second Vice-President*—Dr. R. L. Banta, of Buffalo; *Secretary*—Dr. W. W. Potter, of Buffalo; *Treasurer*—Dr. X. O. Werder, of Pittsburg; *Executive Committee*—Dr. A. Vander Veer, of Albany; Dr. C. Cushing, of San Francisco; Dr. W. H. Wathen, of Louisville, Ky.; Dr. C. A. L. Reed, of Cincinnati; Dr. H. B. Hill, of Saco, Me.

The Association on meeting in Cincinnati numbered thirty-eight members of whom twenty were present. Fifteen new members were added at the Cincinnati meeting. Place of next meeting, Philadelphia, third Tuesday, Wednesday, and Thursday in September, 1890.

### THE PRESIDENT'S ADDRESS.

The President, Dr. William H. Taylor, of Cincinnati, in his annual address, congratulated the Association on the success of its first meeting at Washington, and on the valuable publication made, and thanked the medical journals for their kindly comments on the work of the Association. He had experienced much difficulty in finding fit topics for remark before a society where all were pursuing the same line of study and similar work. Among the many suggestions and proposed changes offered the profession many were ephemeral and lost their interest as soon as something newer was presented. Others had a permanent value and were incorporated into the creed and practice of scientific medicine, while some were useful in revealing error, though they may not discover the truth.

One very satisfactory feature of the year's progress in our department of medecine is the successful effort at increased accuracy in diagnosis, and to more definitely determine the indications for operative procedure. The condemnation of laparatomy is much less frequent than formerly, because of more accuracy in diagnosis, and increased experience has determined proper cases for operation.

The recent lecture of Sir T. Spencer Wells and the statistics of Munchmeyer show the propriety of uterine extirpation, and Wells' terse words, "The best means to prevent return is to operate early," must become an aphorism for our guidance; the very essential factor, ability of early diagnosis, is still a desideratum.

The low death-rate of myomata and the great mortality from operation for their removal suggest the propriety of rare resort to such operation. The brilliance of operative procedure obscures other work, and the apparently greater gravity of a case justifying an important operation diverts attention from suffering less severe; such minor ailments are, however, just as needful of care.

Schultz's and Herman's recent publications regarding uterine displacements are likely to improve our management of such cases.

Subjects which seem to be definitely settled are again revived and become the theme of active controversy, of which fact the discussion of the phenomena and conduct of the third stage of labor is an instance. We all know that debate on this topic has continued for several years in Germany, apparently with little benefit either to the combatants or to science, but the subject assumes much practical importance after the statement recently made by Duhressen, that "one woman dies every day in Prussia from post-partum hemorrhage." Remembering that this fatality can occur only among a limited portion of our population this would seem a large mortality. Assuming the period during which it could occur to be between the age of fifteen and fifty, we should have, according to our census reports, one death from hemorrhage after delivery in less than two hundred from all causes among women in the period mentioned.

The great confidence we have had in the usual method of dealing with the placenta might lead us to the belief that we should be exempt from such disaster, but just now our idols are being shattered, and a man as eminent as D. Berry Hart has said, "I consider the Credé the most dangerous plan possible for the separation of the placenta."

With these facts and these statements so much at variance with the generally accepted opinions, certainly it is the part of wisdom to survey the ground carefully upon which our confidence is built.

The very satisfactory results of Cæsarean section, recently, establish it as an operation which must be resorted to if the obstetrician would escape censure, and the success of the Porro operation modification must lead us carefully to determine to which cases it is adapted and to which Saenger is the more appropriate.

Ectopic pregnancy, pelvic suppuration, and craniotomy have occupied such large place in our recent literature, and are to have such consideration in our programme, that it would be superfluous to devote time to their discussion here.

A review of the progress in our branch of medicine during the past decade is a source of astonishment and a cause of congratulation, for no department can show such additions to life and comfort, but I need only make the assertion to elicit your assent that there yet remains very much land to possess. With the intelligent restlessness which characterizes the educated mind we must press forward, and no prophetic power is required to predict that great progress will be made.

The recent advances in all departments of science, and the wonderful practical application of newly acquired facts disarm incredulity, and we dare to place no limit on the possible acquisitions of the near future.

The Utopias of to-day may be the familiar dwelling-places of to-morrow, and actuated by the noble sentiment which so characterizes our profession, of seeking the truth for the truth's sake, we may be sure of grand additions to our knowledge and skill, and I can utter no better benediction than the hope that this Association may bear its full share in making these acquisitions.

Dr. R. B. Hall, of Cincinnati, O., read a paper entitled

### SOME POINTS IN THE DIAGNOSIS OF PYOSALPINX.

The author believes the importance played in the production of suffering by this disease has not received the attention which it merits. The general practitioner sees and treats the great majority of these cases before they are seen by the operator, and if it is hoped or expected to afford relief to a great number of suffering women all over the land the subject of diagnosis must be better understood than at present. The importance of septic infection in the production of inflammatory disease of the uterine appendages is the cause of these diseases in a large percentage of cases. Repeated attacks of acute exacerbations from perhaps trivial causes, finally produce complete closure of the ends of the tubes. As a consequence the normal secretions of the tubes soon become pathological and by repeated attacks of inflammation may become changed into pus, producing the typical pyosalpinx. The speaker is convinced that this affection frequently follows puerperal diseases and gonorrhœal infection, but does not

consider these the most common causes of the disease. He believes pyosalpinx to be contracted in two different ways: (*a*) By a chronic process, causing dropsy of the tube, which, by repeated attacks of inflammation, is changed to pus; (*b*) it may be rapidly produced by an acute process following gonorrhœa and puerperal diseases. A history of almost constant suffering for years, directed to a certain locality, perhaps originating in an attack of pelvic or abdominal inflammation, connected or not with parturition. To this may be added sterility, and we have a most important aid to a correct diagnosis in the history of the case. Diseased appendages can usually be recognized by a vaginal examination, yet this is not always possible. In most cases it is difficult, and in many impossible, to make out the exact disease of the appendages except in cases of pyosalpinx. We usually have an irregular ovoid tumor, showing swellings and contractions not found in any other pelvic tumor but tubal collections. This tumor is generally of small size; it may be in the retro-uterine space extending toward the pelvic brim on the one side, with a second tumor on the other side higher up; or it may be distinctly felt as a narrow furrow, which is occasioned by a portion of the uterine end of the tube remaining undistended by pus, while the distal end of the tube is enlarged to form the tumor. This furrow is not so plainly felt in those cases where there is a periodical discharge of the pus through the tube into the uterine cavity. This is a very valuable sign to help in making a diagnosis. If we have all the other symptoms of pyosalpinx with a history to confirm them, where we can feel the enlarged tube before a discharge of pus from the uterus, and immediately after the discharge has occurred we find that the tube has collapsed, then we have proof positive of the existence of pyosalpinx.

If the previous history of the case be carefully learned and given due weight and consideration, the author believes the diagnosis is not so difficult as usually thought. The uterus is more or less fixed and misplaced. In the majority of cases seen by him there has been pain during defecation—particularly where the tumor occupied the retro-uterine space. Most cases gave a history of dyspareunia. If pain has long been a prominent symptom and it is evident the tube contains pus, the case must be looked upon as serious and demanding prompt relief. Delays are dangerous, as the bursting of the tube may cause fatal peritonitis, and escape should be afforded the offending pus by removal of the tube.

## AMERICAN ORTHOPEDIC ASSOCIATION.

*Third Annual Meeting, held at Boston, Mass., September 17, 18, and 19, 1889.*

FIRST DAY, TUESDAY, SEPTEMBER 17TH—MORNING SESSION.

THE Society was called to order by the President, DR. E. H. BRADFORD, of Boston, who read an address on

AMERICAN ORTHOPEDICS.

DR. V. P. GIBNEY, of New York, read the first paper, entitled

THE TYPHOID SPINE.

He called attention to a group of symptoms pertaining to the spinal column as a sequel to this fever, and as an anatomical diagnosis used the term "perispondylitis," meaning an acute inflammation of the periosteum and the fibrous structures which hold the spinal column together. He gave the details of three such cases, all of which were acute and ran a benign course. As pertinent to this subject he spoke briefly of a similar condition in which the hip was affected, and presented the photographs of a second case in which the thighs were sharply flexed upon the pelvis, and the legs on the thighs, so that the heels touched the buttocks.

DR. L. A. WEIGEL, of Rochester, by invitation, read a paper entitled

THE RELATION OF THE THORACIC AND ABDOMINAL WALLS TO THE SPINAL COLUMN, CONSIDERED WITH REFERENCE TO THE TREATMENT OF ANTERIO-POSTERIOR CURVATURE.

His conclusions were as follows: 1. The spinal column in its general upright position is supported by the abdominal viscera, or rather by the resistance of the abdominal walls. Following the force of gravity, the spinal column sinks downward until a resistance is met with. This resistance may be produced by a direct support upon the viscera, or indirectly by pressure exerted through the elastic thorax and diaphragm upon the abdominal organs, which are thus forced against the muscular walls until an equilibrium of forces is established. 2. By the support which the abdominal viscera give to the spinal column and thorax, the abdominal muscles very materially supplement the action of the erector muscles of the spine, by increasing the resistance which the viscera offer to the forward inclination of the spine and thorax. 3. The backward inclination of the spine is limited by the tense abdominal muscles and the firm linea alba to which they are attached.

DR. DILLON BROWN, of New York, read a paper entitled

PSOAS CONTRACTION AS A SYMPTOM.

He briefly outlined the various diseases in which this condition may be found, and gave their diagnostic points, especial attention being paid to those phenomena by means of which each disease could be excluded.

DR. A. B. JUDSON, of New York, read a paper on

THE PREVENTION OF THE SHORT LEG OF HIP DISEASE.

He set forth the importance of inducing the patient who wears the hip-splint to observe the natural rhythm of the gait in walking, dividing the time on the ground equally between the two feet, or rather between the well foot on one side and the hip-crutch of the splint on the other side. He believes that if the patient, by precept and drill, is induced to walk habitually in this way the affected limb will incline toward abduction, in order to reach the ground and do its share in the work of locomotion. Adduction and flexion, which constitute the dreaded short leg of hip disease, are caused by the patient's efforts to keep the limb off the ground, partly to guard against concussion, and partly to keep the limb out of the way of its fellow, which is charged with the chief part of the work of progression. If the affected limb, protected from concussion by the splint, habitually seeks the ground and is active in locomotion, the cause of adduction and flexion is removed. He cited cases illustrating his views.

DR. BERNARD BARTOW, of Buffalo, read a paper entitled

THE IMMEDIATE DISREGARD OF MALPOSITION OF THE THIGH IN THE TREATMENT OF HIP DISEASE.

He employed the following method in the earlier stage of the disease. It was a fixative dressing of plaster of Paris, which was applied while the patient was suspended, as during the application of the plaster jacket in spondylitis. The well foot is allowed to rest on a block from four to six inches in height, so that the affected limb will, by its own weight, exert traction upon the muscles about the hip-joint. The plaster of Paris is applied over the trunk, hip, and leg, extending above to the sixth rib and below to the middle of the leg. The dressing is strengthened by strips of thin malleable steel. No attention is paid to the malposition, which is gradually overcome by the weight of the leg as different splints are applied, the rest afforded the joint during these intervals removing each time much of the spasm. The author reported his cases, and showed photographs of them.

AFTERNOON SESSION.

DR. C. C. FOSTER, of Cambridge, read a paper entitled

A CASE OF CARIES OF THE ANKLE TREATED CONSERVATIVELY.

After giving a detailed report of the case and its treatment, he exhibited the patient and plaster casts of the foot before and after treatment. He maintained that such treatment is not nearly so quick, so easy, or so striking as a successful resection, but that the final result is far superior, and well repays the extra time and great patience which must be devoted to the case. He did not claim that all cases should be treated in this manner, but that in many cases an intelligent, enlightened conservatism, properly carried out, will produce the best final results.

DR. C. L. SCUDDER, of Boston, by invitation, read a paper (with exhibition of patients) entitled

A REPORT OF CASES OF CARIES OF THE ANKLE TREATED BY EXCISION.

From the study of his cases, he drew the following conclusions: Excision is safe, and the mortality is not great. The convalescence and time of after-treatment are short. The disease in the foot is ended, and the prognosis is sure. Profuse suppuration and its consequences are avoided. The likelihood of septic infection is at a minimum. The partial operation of curetting is of very little value. There is no mutilation of the foot, and its usefulness is very great after excision. The question of tubercular infection after operative interference is yet unsettled. Excision of all the diseased bone should be resorted to earlier in the treatment of chronic ankle-joint and tarsal disease.

DR. JOHN RIDLON, of New York, read the report of a

CASE OF CONGENITAL DISLOCATION AT THE HIP.

The patient, a female, aged ten and one-half years, came under observation nineteen months ago. The right great trochanter was two and one-half inches above Nélaton's line, and it required a blocking under the foot of three inches to make her stand fairly erect. The old pattern of the Taylor extension hip-splint was applied, and the leg elevated on an inclined plane. For one year the child did not leave her bed, and no relaxation of the traction was once permitted. At the end of this time it was possible to locate the head of the femur, which was found to be displaced upward and forward, lying almost directly below the anterior iliac spine, and the difference in the length of the legs was found to be reduced to half an inch. A jointed splint was applied, February 1, 1889, and the patient was allowed up.

DR. J. E. GOLDTHWAITE read a paper prepared with DR. R. W. LOVETT, of Boston, entitled

ABSCESSES IN HIP DISEASE: THEIR PREVENTION, SIGNIFICANCE, AND TREATMENT—A CLINICAL STUDY.

Three hundred and twenty cases were analyzed with reference to the number of abscesses occurring and the effect of treatment. In these cases, seventy-five abscesses occurred, which very small percentage is attributed to long-continued treatment with the long traction splint in the line of deformity, if present, and fixation in bed. The majority of the abscesses occurred in patients in whom there had been insufficient and careless treatment at home. The abscess in fifty-nine per cent. came early in the course of the disease, *i.e.*, within one year of the beginning of treatment, and in forty-four per cent. the abscess came on before treatment had been begun. He concluded that the preventive treatment in hip abscess was an exceedingly important matter, and that the abscess may be averted in a large proportion of the cases under efficient treatment by confinement of the patient to bed when symptoms of deformity or joint tenderness arise. But that when this smaller proportion of abscesses had occurred, in them the mortality was exceedingly high and the prognostic outlook very much more serious than in suppurating hip disease in general. Operation, in all of these cases, was not accompanied by anything approaching septicæmia, nor did it prevent the occurrence of tubercular meningitis or amyloid degeneration; and, finally, it was stated that thorough operation is followed in a fair proportion of all cases by speedy closure of the sinuses, a closure which remains permanent.

---

SECOND DAY, WEDNESDAY, SEPTEMBER 18TH—MORNING AND EVENING SESSIONS.

These sessions were devoted to the reading of short papers on hip disease, which were followed by a general discussion of the subject by the members of the Association.

DR. H. G. DAVIS, of Everett, exhibited a

HIP-SPLINT

which showed many valuable modifications of the original splint which he invented many years ago, and which has formed the basis of all the traction hip-splints.

DR. N. M. SHAFFER, of New York, read a paper on

THE PRINCIPLES OF TREATMENT OF HIP-JOINT DISEASE.

He held that hip-joint disease is a tubercular disease characterized by an insidious invasion and by a limp, and a muscular splinting of the diseased joint. The muscular splint, acting in the direction of the long diameter of the muscles, made a direct interarticular pressure, and was nature's method of affording protection to a diseased joint. Dr. Shaffer illustrated the action of traction in protecting a diseased hip by calling attention to the effect of manual traction in a child suffering acutely from hip disease, and he further illustrated the subject by showing that it subjected the patient to severe pain if we used the lever principle, making the joint a fulcrum to overcome the muscular deformity, thereby still further increasing the interarticular pressure. He spoke only on the general principles, and mentioned no particular form of apparatus. He stated that his experience had led him to say that the lever principle of treating hip disease was crude and unscientific. Certainly it was not the correct mechanical principle to apply to an already overburdened and overtaxed joint. And that true rest, real immobilization, and perfect fixation, when these elements were required in the treatment of hip-joint disease, were best obtained by some form of apparatus employing the traction principle.

DR. A. J. STEELE, of St. Louis, discussed

THE EARLY LOCAL TREATMENT.

He said that the earlier correct treatment was commenced, just so much better would be the result. The reason we had fewer deaths, less deformity, and better average results to-day than formerly, was because the cases were recognized earlier, were subjected to treatment at an earlier stage, and because of our improved therapeutics. He said that the members of this Association could not too often or too emphatically instruct the profession at large regarding the serious import of lameness and pain in the child. Our ideas upon the correct treatment of this affection turn upon what we believe to be the pathological process going on within or near the joint. The means by which the needed rest may be furnished the joint, without interfering with the proper hygienic treatment, was obtained, he thought, by the "stretcher splint," which consists of an iron frame covered with canvas upon which the child lies. By movable attachments, extension and counter-extension may be obtained, and the trunk is fixed to the frame by straps. Perfect immobilization can be thus secured, and at the same time the patient may be moved from place to place in the open air and sunlight. He exhibited his apparatus, and stated that cases seen early and thus treated had no abscesses, and obtained useful joints.

Dr. De F. Willard, of Philadelphia, spoke upon

THE OPERATIVE TREATMENT.

His conclusions were: 1. Mechanical measures that enforce strict and long-continued restriction of the joint are preventatives of operative procedures. 2. That an operation is in itself a confession of failure to arrest the inflammation. 3. Antiseptic aspiration of the joint is advisable when it is distended with serum, and sometimes when it is full of pus. 4. Ignipuncture, trephining, and drilling give great relief, provided the focus of disease is not extensive. 5. If in doubt as to the presence of pus, use rest and fixation, and wait; or aspirate antiseptically, and, if no true pus is found, continue the immobilization. Should the aspirator disclose a thin sero-purulent material, continue the aspirations as needed until absorption takes place, or until positive signs of pus are present. 6. When certain that pus is present, and in those cases in which the patient is doing badly, make an exploratory incision, open the abscess, and follow by one or the other of these two plans: (*a*) Wash out the abscess-cavity antiseptically, but on no account attempt, by pressure, to expel the pus, lest fissures be produced in its walls, and bacillary infection occur; or (*b*) continue the exploratory incision down along some sinus, thoroughly examine the joint, and remove thoroughly every particle of tuberculous tissue of both hard and soft parts. 7. Do a formal incision only when the bone disease is found to be too extensive to be removed in any other way. 8. Always follow operative procedures by the most thorough attention to fixation and protection of the joint for years.

Dr. R. H. Sayre, of New York, discussed

EXCISION OF THE HIP.

He said that with proper mechanical treatment, commenced early in the disease, and with good hygienic surroundings, the vast majority of cases recover without excision and recover with limbs as good or better than those resulting from excision. The primary focus of the disease is usually so situated that it cannot all be removed without excising the joint. About half the primary excisions relapse, a number are followed by general tuberculosis, and the result is not equal to that of mechanical treatment. Therefore do not excise in the onset of the disease. The development of an abscess is the last step in nature's process of exfoliating the diseased tissues, and in such cases to excise is a mistake, and the abscess alone requires treatment. In other cases, however, the patient, in spite of treatment, does badly, and it is in such cases that it is necessary for the surgeon to interfere and excise the joint, not delaying until the patient is worn out with fever and suffering from amyloid changes. But, even in such cases, when the diseased tissue is removed, the patient may recover. The author then gave the technique and the after-treatment of the operation.

Dr. A. B. Judson, of New York, discussed

THE TREATMENT OF HIP DISEASE.

He had been unable to recognize the trauma which is said to be caused by reflex spasm. It implies a vicious circle in which spasm causes inflammation, and inflammation, in its turn, causes spasm. He was also sceptical in regard to the alleged counteraction of the muscles by traction. He believed it mechanically impossible to make useful traction on the muscles which cross the line of the joint with adhesive plaster applied over the skin. The great relief comes from the fact that traction is attended by practicable, comfortable, and beneficial fixation of the joint. He raised the question whether we are not responsible for the apathy with which the profession regards the treatment by the hip-splint. We claim so much for it and the things we try to do with it are so mysterious and require such nice and fanciful adjustments that the practical common-sense of the profession in general is likely to continue to neglect an apparatus of the greatest utility and value. He doubted the permanent efficacy of operations on the femur for the correction of any except the most extreme deformities. The angle established in the bone after osteotomy is of course permanent, but he would expect adduction to recur at the point of fibrous anchylosis.

Dr. John Ridlon, of New York, read a paper entitled

FIXATION AND TRACTION IN THE TREATMENT OF HIP-JOINT DISEASE.

He believed that the treatment of inflammation in and about the hip-joint should in a general way be governed by the same principles which govern the inflammation of like character in other parts of the body, and that physiological rest of the inflamed structures is the chief end to be obtained. By physiological rest he meant relief from the performance of the normal functions. The functions of the hip-joint are motion and the sustaining of weight; therefore, as applied to the hip-joint, rest is relief from motion and from the sustaining of weight. The problem, then, would seem to be, in so far as it is possible, to immobilize the joint so long as any inflammation remains. To remove the superincumbent weight until convalescence is well established and to counteract the effect of muscular spasm, so long as that spasm is in any way harmful, are the indications. He discussed the means of fulfilling these indications and urged that fixation should be made as perfect as possible, depending upon the surrounding circumstances of the patient. If traction be used at all, it should be constant and in the same line. Traction at right line at one time and at right angles at another, as is permitted by most forms of traction apparatus, cannot be free from harm, and the push and pull action of all traction hip-splints during locomotion must be seriously condemned.

Dr. V. P. Gibney, of New York, discussed

MECHANICAL VS. OPERATIVE TREATMENT,

and in a very complete comparison gave the indications and limitations of each line of treatment.

---

Afternoon Session.

Dr. E. G. Brackett, of Boston, read a paper entitled

AN EXPERIMENTAL STUDY OF DISTRACTION OF THE HIP-JOINT.

The points in this paper include the consideration of the counteracting influence of the bony formation of the joint, of atmospheric pressure, and of the assisting force of ligaments and muscles. In adults, owing to the bony formation of the joint, traction is mainly expended in pulling the most dependent portion of the head of the femur down on the bottom of the acetabulum, which offers a mainly horizontal surface. When separation occurs it is denoted by a widening at the hips as well as by lengthening of the leg. The child's joint offers no such resistance to the traction force, but allows a separation nearly in the line of traction and is shown principally by a lengthening of the limb. Experiments showed that atmospheric pressure played but a very unimportant part in preserving contact while the parts were intact. It was shown that the counteracting force of muscular action was the most important influence, and this must be accomplished either by muscular tonicity or muscular contraction. The claim was not made that distraction is an inevitable result of traction, nor even that it is possible under all conditions, but that this does occur in children under favorable conditions when the power is properly applied.

Dr. John H. Huddleston, of Boston, read a paper entitled

AN ANALYSIS OF TWENTY-ONE CASES OF HIP DISEASE TREATED BY THE THOMAS SPLINT.

No attempt had been made to choose cases for the splint. It had been applied in all stages of the disease, and in some cases it was kept on throughout the course of the disease and in others until the interests of the patient demanded a change. Cases were seen once a month or

oftener and were taken from the ordinary class of out-patients. It was found difficult to fit the splint, and more difficult to fix the splint after being fitted. Of the twenty-one cases, satisfactory notes were obtained in fourteen, and notes sufficient to explain the use and the result of the splint in five more. One patient died shortly after the application of the splint and one had not been heard from. The results obtained were stated as follows: Good position with both flexion and adduction, but great shortening, great atrophy, and very constant elevation of the trochanter above Nélaton's line with a remarkable percentage of abcesses.

The Society then inspected the Boston Children's Hospital, and were shown by Dr. H. L. Burrell many cases of great interest.

---

THIRD DAY, THURSDAY, SEPTEMBER 19TH—MORNING SESSION.

DP GEORGE W. RYAN, of Cincinnati, read a paper entitled

WHEN MAY TREATMENT BE DISPENSED WITH IN SPONDYLITIS?

It was a matter which had a wide interest to every orthopedic surgeon, and was never an easy question to determine. He believed that as a rule the orthopedic surgeon left the apparatus on too long, and that the general surgeon removed it too early. He had seen many cases of spondylitis in which the appliance had been removed too early, and many others in which he was satisfied that it was kept on too long. He stated that a slight increase in a kyphos which is already well marked makes a very great change in the gait, the appearance, and the growth. He believed that when the disease was no longer present the appliance was a foreign body and retarded muscular growth and exercise. He believed that no general rule could be laid down concerning the time when treatment could be dispensed with, but that some indications might be pointed out. He thought that the type of patient largely influenced the course of the disease. Absence of pain was of little value, as efficient support always relieved that. The speaker often found the compensating depression beneath the kyphos indicative of cure. Many cases of cervical and lumbar disease get well without treatment and with fairly good results. The matter requires a great deal of care, and the appliance should be slowly dispensed with. Massage, cold baths, and faradism were of great service at this time.

DR. W. R. TOWNSEND, of New York, read a paper entitled

ACUTE ARTHRITIS OF INFANTS.

It was essentially an osteo-myelitis, the difference in pathological conditions being largely due to differences in anatomical conditions and relations of the epiphysis to the joint. Various forms of staphylococci were found in some cases, notably *S. aureus* and *albus*.

The symptoms are quite constant—flexion of the joint, production of abscesses, involving the joint and soft parts, and constitutional symptoms of pyæmia. The treatment was early and complete evacuation of the inflammatory products and heart-stimulants and tonics. Most cases occur in patients under one year of age, and about fifty per cent. of them result fatally. He reported seventeen cases, and from the experience of these and others found that the joints most affected were the hip, knee, and shoulder.

DR. A. J. STEELE, of St. Louis, showed a

NEW EXERCISE IN THE TREATMENT OF LATERAL CURVATURE OF THE SPINE.

He showed an apparatus for fixing the feet firmly to the ground, thus securing fixation both below and above.

The Secretary read a paper by DR. T. H. MEYERS, of New York, reporting a case of

TRAUMATISM OF THE HIP SIMULATING THYROID DISLOCATION.

It was the result of a fall in a child nine years of age. The patient struck upon the left hip and the injury was immediately followed by a limp, but little pain, and presented the following condition: The patient stands with the left thigh advanced, the knee slightly flexed, and the foot in equinus with 45 degrees of outward rotation of the thigh. In the supine position there was flexion at the hip of 160 degrees and abduction of 30 degrees; and when the legs are approximated the left leg is apparently one and one-quarter inch longer than the right, but there is no real difference in the length. There is marked depression over the trochanter major, and the trochanter is three-eighths of an inch above Nélaton's line. On flexing both thighs to 90 degrees the left knee is an inch higher than the right, but all these facts seem to be due to the abduction. Adduction and extension are impossible. Rotation, abduction, and flexion are allowed to a considerable extent, and when limited there is not the reflex spasm of joint disease. Under ether the flexion and abduction disappeared, but adduction and extension were still restricted. It was probably a separation to a greater or less degree of the cotyloid ligament and the bone.

DR. V. P. GIBNEY, of New York, presented a paper entitled

A CONTRIBUTION TO THE STUDY OF FLAT-FOOT.

In some cases painful flat-foot was accompanied by ingrowing toe-nail, and he reported one case and referred to two others in which the removal of the offending nail resulted in a marked improvement in the condition of the flat-foot.

---

AFTERNOON SESSION.

DR. N. M. SHAFFER, of New York, read a paper entitled

THE TREATMENT BY PORTATIVE APPLIANCES OF UNUNITED FRACTURE OF THE FEMUR.

The writer reported three cases. In the first a long traction splint with a felt coaptation splint was applied and traction was maintained, the patient walking about on it in the meantime. In two and a half months it was united, with three-quarters of an inch of shortening. The second was also a case of ununited fracture of the shaft of the femur, following treatment by Buck's extension. The long traction splint was applied, and this was followed by a traction splint which permitted knee-joint motion and also independent traction to the thigh and leg. In this way passive motion to the knee was given during treatment and the union was completed in two months, with practically no shortening. In the third case there was an ununited fracture of the neck of the femur, with three inches of shortening. A traction splint like that in the second case was applied, with the addition of a "surcingle," which was buckled tightly about the trochanter. Union was completed in three months, with five-eighths of an inch of shortening.

DR. R. W. LOVETT, of Boston, reported

A CASE OF FUNCTIONAL TORTICOLLIS, PROBABLY DUE TO DEFECTIVE EYESIGHT, WITH EXHIBITION OF PATIENT.

The patient was three years of age, and the torticollis was noticed by the parents six months before the patient came under treatment. There was an internal strabismus, and as soon as the recti were cut there was a decided improvement in the wry neck. The recovery from the torticollis was not complete, but, as a slight internal strabismus still remains, it was expected that after another operation for the insufficient recti the recovery would be complete.

Dr. W. N. Bullard, of Boston, read a paper, prepared in conjunction with Dr. H. L. Burrell, the title of which was

OPERATIONS UPON THE SPINE FOR THE RELIEF OF PRESSURE PARALYSIS.

Twelve cases were reported, and the summary was as follows: Contra-indications—1, Those cases in which an operation would not be advisable, from the general health or other general surgical considerations; 2, the presence of tuberculosis in other parts of the body; 3, the presence of an abscess with the caries which can be otherwise evacuated; 4, acute exacerbations without symptoms referable to the cord, and not threatening life. The indications in favor of an operation were: 1, General good conditions and favorable surroundings—(*a*) when the disease is gradually and slowly progressing to an unfavorable termination, and (*b*) when the patient has more or less loss of motion and sensation in the portions of the body below the level of the lesion and incontinence of urine and fæces, and when these conditions have lasted for a sufficient length of time to render spontaneous recovery improbable, and not so long as to produce permanent destruction of all recuperative power in the cord; 2, when acute symptoms threatening life appear, and when there is reasonable expectation that they may be relieved by the removal of the compression.

Dr. Homer Gage, of Worcester, by invitation, reported

A CASE OF CONGENITAL ABSENCE OF FIVE RIBS, WITH RESULTING DEFORMITIES.

The sixth to tenth inclusive on the left side were absent, and in consequence of their absence there had developed a rotary lateral curvature of the spine, a hernia of the stomach, and a displacement of the heart on to the right side. Photographs showing these conditions accompanied the paper.

It was decided to hold the meeting next year in Philadelphia, and the following officers were elected: *President*—Dr. De F. Willard, of Philadelphia; *First Vice-President*—Dr. A. J. Steele, of St. Louis; *Second Vice-President*—Dr. A. B. Judson, of New York; *Secretary and Treasurer*—Dr. G. W. Ryan, of Cincinnati; *Corresponding Secretary*—Dr. Samuel Ketch, of New York.

The following statement was adopted as expressing the opinion of the Association in regard to the treatment of hip-joint disease: 1. In the painful stage, complete rest to the joint is of the first importance. 2. Early excision is to be condemned. 3. The weight of the body should be removed from the affected joint until complete recovery has taken place. 4. Traction is an important element of treatment.

---

Some Domestic Remedies in the Transvaal.—Mr. Walter H. Haw, in a letter to *The Lancet* upon medical practice in the Transvaal, gives the following list of remedies in which the Boers have the most implicit faith, and to which they recur in many of the ills of themselves and their families: 1. Cow-dung poultices. 2. Stink blaar (*Datura stramonium*) leaves applied for the relief of pain. These act well, and are often used. 3. Prickly-pear leaves skinned and applied. 4. For children: A young goat killed and opened, the child being put in bodily after removal of the viscera. A good poultice, I fancy. 5. Rimpis (threads) of eel-skin worn round the painful joints in chronic rheumatism. This was described to me by a man who was wearing one round almost every joint of his body as being a splendid remedy. 6. Rimpis of the tanned skin of a tame goat worn as above for sprains, etc. 7. The finely chopped hair of a black cat, which should not have the faintest trace of white about it. A remedy for convulsions. 8. A spoonful of dog's blood taken from the ear for "buur en de mag" (inflammation of the bowels). 9. For snake-bite, repeated fowl poultices.

# New Instruments.

## THE QUESTION OF THE POCKET-CASE.

By ROBERT H. M. DAWBARN, M.D.,

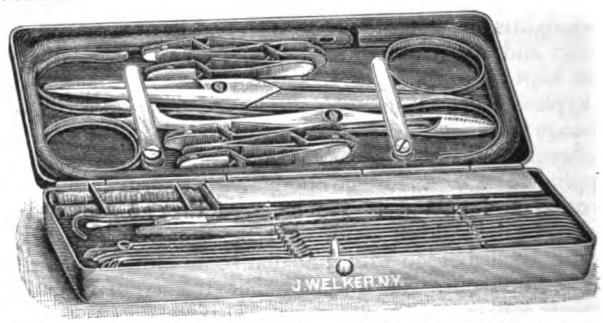
LECTURER IN OPERATIVE SURGERY, NEW YORK POLYCLINIC.

In common with many others I have felt interested in the letters from various medical men which have appeared in these columns of late, discussing the question of the ideal pocket-case for surgical instruments. Considerable space in these communications has been devoted to the case itself, and not so much as I could have wished to its contents.

This is a subject upon which I have had to think somewhat, for each year there are a dozen or more men about entering professional life who ask me, as their preceptor, what is best for them to purchase at the outset in the way of tools of the trade, so to speak.

It is an unfortunate fact, which I think no surgeon will deny, that the pocket surgical cases and contents now on the market are, almost without exception, an abomination in the eyes of the surgically cleanly; and the instruments are, furthermore, in many respects inefficient in point of proper selection to meet the needs of any emergency operation much graver than lancing a boil.

Surgery has advanced; but, with few exceptions, the cases we carry upon our persons are those familiar to our fathers.



The leathern receptacle is prettily lined with velvet, and cannot by any possibility become purified when, in process of time, it has become strong with sweat and grimy with dust which a tap of the finger will bring forth from the lining.

Into this the instruments go. And what instruments! The knives have baby-blades—fit only for playing at surgery. There is the inevitable curved, sharp-pointed bistoury, the pet of those whose idea of surgery is to stab in the dark and cut out. Of course no one is brutal enough nowadays to incise a felon or a boil without some kind of local anæsthesia; hence this bistoury loses its one poor excuse of completing at a stroke its incision when the patient in agony shrinks suddenly away from the surgeon. These knives, at the best, have some patent arrangement whereby, although they close up, the blade can be detached, permitting the handle to be cleansed—with difficulty. And at the worst, and usually, they are as hard to disinfect as the ordinary pen-knife.

Sometimes we actually find the jointed metallic catheter in our case. A little use always makes its joints misfits. I wonder how many physicians would be willing to have their water drawn by one of these things which was not fresh from the instrument-maker?

Will someone of an intellectual turn of mind inform me why it is generally considered *de rigueur* to limit the number of artery-forceps in the pocket-case to one? Out of dozens of these cases I have never seen any with more than two hæmostatic forceps, which number is all too little. If an emergency case demands treatment of hemorrhage at all, it will almost surely need more than one or two clamps for bleeding vessels. The custom, I find, is to kill two birds with one stone by making the other end of the artery-forceps a needle-holder—or some-

thing else—and the combination is, of course, difficult to clean.

In this latter regard I cannot refrain from expressing my admiration equally for the business thrift which induces the instrument-dealers to stamp their names as an advertisement into the metal of our tools, and for the Christian resignation with which a long-suffering profession has tolerated this means of propagating filth. If a surgeon's time is of any value he does not wish to waste it in digging particles of foreign matter with a needle out of the letters stamped into his scalpels and scissors, and which the brush will not entirely remove; and if he is not thus careful he will probably have "laudable pus" in his wounds—to his shame.

How about our ligatures and sutures? These we shall find in the form of a strand of silk wound on a card and placed in a pocket of the case. Woe to the wound!

The essence of primary antisepsis is asepsis, and asepsis is strict cleanliness. Therefore let us use only tools which are easily kept surgically clean. If possible, we should have each tool of one piece of smooth metal, shaft and blade. If two parts are essential, these should be smooth too, and easily detachable for cleansing. Cross-hatching upon handles, etc., is worse than useless. The idea, of course, is to give security to the grip; but no one needs to grip these instruments.

To surgeons all the foregoing will be trite, and as a many-times-told tale. But that it needs repetition for the profession as a whole a visit to the nearest instrument-shop will convince anyone. The dealers keep in stock what is found still salable.

Among the correspondents of THE MEDICAL RECORD is one gentleman who advocates a case made of chamois-skin, as being easily cleansed by washing, and readily made at home. This is a step in the right direction, but has two objections: First, the bulk is about as great as that of the leathern wallet; second, with the scalpel which I have advocated, and which is not a claspknife, the blade would probably cut its way through the chamois-skin.

My object in writing this article is not alone to criticise; it is also to offer a case of my own for criticism, and, I hope, for approval. First let us discuss the case, then its contents.

I. An ideal case should be of smooth, plated metal, that it may be easily cleansed; may be boiled, if thought desirable. It should not be appreciably heavier than the leathern pocket-case; hence the metal must be very thin. It should be as small as possible, and of such a shape as not to cause the pocket in which it is carried to bulge, and thus make a coat fit badly.

These points are covered in my case. Of course the idea of a metallic case is not new. It originated in Germany, I believe. But generally they are too thick and heavy. They should be as wide as the top waistcoat-pocket will carry, and this width permits them to be of less depth than otherwise.

The cut of the case shown herewith is, of course, reduced in size. The actual case has no name upon it (differing from the cut), neither is there a name or an unnecessary scratch upon any instrument. A close-fitting chamois-skin cover goes over the case, for use, if thought best, to prevent the slipping of so smooth an object from the pocket.

The case and instruments are made by Welker, next door to the Polyclinic.

II. The following is the list of instruments: 6 stout artery-clamps; 1 pair of scissors, straight, with French-lock; 1 needle-holder (French-lock), which is also a dressing-forceps and a sequestrum-forceps; 1 very narrow-bladed scalpel; 1 straight, blunt-pointed bistoury; 1 pair of two-hooked retractors; 1 Peaslee's needle (long, with handle, eye in point); 2 pairs of dissecting-forceps; 1 metacarpal saw; 1 Volkmann's sharp spoon, medium size; 1 grooved director and aneurism-needle; 2 silver probes, one of them eyed; 1 small metal box with tight cover—this contains a silver *porte-caustique*, an assortment of needles, including Hagedorn's, and in a small compartment a few bichloride tablets wrapped in rubber-tissue; 2 bottles, tightly corked, in a metal frame; one contains catgut, the other silk, each tightly wound on a small reel, and in an antiseptic solution; 1 rubber soft catheter, medium size. This serves three purposes: that of a catheter, a means of bloodless operation upon the smaller members, and, in the case, as a buffer, preventing by elastic pressure any noise or rattling of instruments.

The knives have long blades and as short handles as compatible with good work. No more than one good scalpel is really needed in an emergency pocket-case; and the surgeon can do things with a narrow-bladed scalpel that he could not with a wider blade—can use it as a tenotome if he needs one.

It seems to the writer that, considering the object we have in view, the list given about covers the ground. As the instruments are all made as light as possible, the total weight is trifling. If more were added the case would have to be larger, and would then become clumsy and bulky, like the leather one. And I hardly think that any of these tools could well be spared. It has been suggested that one pair of thumb-forceps is enough. But when working in a dangerous region it is safer to use two pairs of forceps than a grooved director, in many cases.

In the bottles the antiseptic liquid preferred is—following the experiments of Dr. G. de Ruyter—one composed of a saturated solution of bichloride-washed iodoform in equal parts of alcohol and ether. The silk is first boiled in a 1 to 500 watery solution of mercuric bichloride, and is then immersed and kept in the iodoform-alcohol-ether. The commercial catgut is first placed for a few days in ether, to remove all the fat thoroughly from its pores, and is then immersed in the same solution (iodoform-alcohol-ether) and kept there permanently. I know of no method compatible with strict antisepsis whereby the strength of catgut and silk is better maintained.

There are very few operations, except some unusual ones upon bone, which really need other mechanical aid than the contents of this case and one or two things always at hand. Exsanguination of a major member needs no Esmarch apparatus in an emergency; elevation and "milking" of the limb, followed by the thorough application of the extemporized "Spanish windlass" suffices admirably. A clean sheet is always to be had; and torn in pieces of proper size, and bichloride-soaked, makes pledgets in lieu of sponges, and also supplies dressings. Still other rolled-up strips of the sheet form bandages.

Bichloride tablets we have, wherewith to disinfect hands, patient's skin, and the dressings, and to irrigate. The instruments, being scrupulously clean, need only be put in pure water. If this needed demonstration, Mr. Lawson Tait has demonstrated it.

There is no need to carry or procure carbolic acid. Carbolic acid is at present little more than a means whereby surgeons testify to their distrust of their assistants, therewith trying to sterilize dirt upon instruments which may have been carelessly cleaned.

---

EFFECT OF CANNON-FIRING ON THE EIFFEL TOWER.—Of all the indispositions (and there are many) created by the Exhibition, the most curious is that which is caused by the firing of the cannon on the Eiffel tower. Every evening, at ten o'clock, when the gun is fired for the last time in the day, it is not unusual to see produced a sort of frenzy among the young female visitors to the Exhibition. Under the already strong impression produced by the illuminations, the luminous fountains, etc., when the gun is fired, they seem to be seized with a veritable panic. It appears to them that a sudden catastrophe, such as a great fire, has taken place. Cries of admiration escape from some, and of terror from others, when fainting, attacks of hysteria, and of prostration occur. The subject has attracted the attention of Professor Charcot and other physicians.—Paris Correspondence of *The Lancet*.

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 6 to October 12, 1889.*

STEINMETZ, WILLIAM R., Captain and Assistant Surgeon. Ordered for examination for promotion. Par. 3, S. O. 236, A. G. O., October 10, 1889.

CARTER, EDWARD C., Captain and Assistant Surgeon. Granted leave of absence for twenty days. Par. 6, S. O. 234, A. G. O., October 8, 1889.

SMITH, A. K., Lieutenant-Colonel and Surgeon. Leave of absence extended twenty-one days, on surgeon's certificate of disability. Par. 7, S. O. 234, A. G. O., October 8, 1889.

MUNDAY, BENJAMIN, Captain and Assistant Surgeon. Granted four months' leave of absence. Par. 2, S. O. 233, A. G. O., October 7, 1889.

*Official List of Changes in the Medical Corps of the United States Navy for the week ending October 12, 1889.*

BRIGHT, G. A., Surgeon. Detached from temporary duty at the Naval Academy, and placed on waiting orders.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 12, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 85 | 8 |
| Scarlet fever | 36 | 4 |
| Cerebro-spinal meningitis | 0 | 0 |
| Measles | 8 | 1 |
| Diphtheria | 73 | 19 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

PULMONARY DISEASES CAUSED BY DUSTY OCCUPATIONS.—Dr. Kunze, in his inaugural thesis for the M.D. degree of the University of Kiel, publishes as a contribution to the diseases caused by the inhalation of dust a series of examinations of lungs so affected. In all these dust was found microscopically, and after chemical tests in the various anatomical and histological parts of the lungs and in the interior of the lymphatic vessels, numerous leucocytes were found covered with the dust. Being arrested in its progress it causes inflammation, producing hyperplasia of connective tissue, especially where a dense net-work of lymphatic vessels exists. Dr. Kunze also proved that the degree of alteration in so-called "dust lungs" depends not merely on the quantity of the dust inhaled, but also on its greater or less morphological power of injuring the tissue. He concludes from his experiments that even the greatest alterations in these lungs—such as nodes, indurations, and vomicæ—are mainly produced by the inhaled dust, and that tuberculosis is only an occasional coincidence. The least serious alterations in the lungs resulted from the inhalation of lamp-black, the particles of which are very fine and little injurious; the most serious, from the dust inhaled by earthenware manufacturers and stone-masons. The lungs of a locksmith showed only a moderate hyperplasia of connective tissue, the dust consisting partly of the finest particles of iron. In a worker in oxides of iron the lungs were found full of small granules, and the morbid changes in the tissues were very considerable. The lungs of gold miners were generally indurated and atrophied; the dust in these cases is exceedingly fine. Sand produced numerous circumscribed hard nodules and thick indurations. In cloth manufacturers the lungs, in spite of the contact with an enormous quantity of organic dust, presented but few indurations. In the lungs of two stone-masons induration and tuberculous disintegration were observed; all the other lungs were entirely free from tuberculosis of any kind, an observation which was verified by the absence of tubercle bacilli in the mucopus in the vomicæ.—*The Lancet.*

AMERICAN PUBLIC HEALTH ASSOCIATION, 1889.—The American Public Health Association will convene at Brooklyn, N. Y., Tuesday, October 22d, at 10 o'clock A.M., and continue four days. The meetings will be held at the Brooklyn Institute. The Executive Committee have selected the following topics for consideration at said meeting: I. "The Causes and Prevention of Infant Mortality." II. "Railway Sanitation. (*a*) Heating and ventilation of railway passenger coaches; (*b*) water-supply, water-closets, etc.; (*c*) carrying passengers infected with communicable diseases." III. "Steamship Sanitation." IV. "Methods of Scientific Cooking." V. "Yellow Fever. (*a*) The unprotected avenues through which yellow fever is liable to be brought into the United States; (*b*) the sanitary requirements necessary to render a town or city proof against an epidemic of yellow fever; (*c*) the course to be taken by local health authorities upon the outbreak of yellow fever." VI. "The Prevention and Restriction of Tuberculosis in Man." VII. "Methods of Prevention of Diphtheria, with Results of such Methods." VIII. "How far should Health Authorities be permitted to apply known Preventive Measures for the Control of Diphtheria?" IX. "Compulsory Vaccination." X. "Sanitation of Asylums, Prisons, Jails, and other eleemosynary Institutions." *Partial list of papers to be presented.*—The following is a partial list of papers to be presented—a full list will appear in the daily programmes: "Address of Welcome," by Hon. Alfred C. Chapin, Mayor, on behalf of the City; "Address of Welcome," by Alexander Hutchins, M.D., on behalf of the Medical Profession; "President's Address," by Professor Hosmer A. Johnson, M.D., Chicago, Ill.; "The United States Census in its Relation to Sanitation," by Dr. John S. Billings, LL.D., Major and Surgeon U.S.A., Washington, D.C.; "Recent Researches relating to the Etiology of Yellow Fever" (illustrated with the stereopticon), by George M. Sternberg, M.D., Major and Surgeon U.S.A., Baltimore, Md.; "More Yellow-Fever Problems," by Jerome Cochran, M.D., State Health Officer, Montgomery, Ala.; "Forms of Statistics," by Henry B. Baker, M.D., Secretary State Board of Health, Lansing, Mich.; "A Suggestion for the Limitation and Detection of Adulterations in Food and Drink," by Henry Leffmann, M.D., Philadelphia, Pa.; "The Prevention of Consumption," by J. N. McCormack, M.D., Secretary State Board of Health, Bowling Green, Ky.; "The Necessity for a More Rigorous Inspection of Meat-producing Animals at the Time of Slaughter," by D. E. Salmon, D.V.M., Chief of Bureau of Animal Industry, Washington, D. C.; "The Causes of Infant Mortality," by Dr. R. O. Beard, Assistant Commissioner of Health, Minneapolis, Minn., and Professor of Physiology in the Medical Department of the Minnesota State University; "Causes and Prevention of Infant Mortality," by Jerome Walker, M.D., Brooklyn, N. Y.; "The Utilization and Purification of Sewage," by John H. Rauch, M.D., Secretary State Board of Health, Chicago, Ill.; "The Art of Cooking," by Edward Atkinson, LL.D., Boston, Mass.; "New Method of Dealing with the Dead" (illustrated with the stereopticon), by Rev. Charles R. Treat, New York City; "Report of the Committee on the Disposal of Garbage and Refuse Matter," by S. S. Kilvington, M.D., Commissioner of Health, Milwaukee, Wis.; "A Suggested Minimum Basis of Compensation to

Local Health Officers," by George Homan, M.D., Secretary State Board of Health, St. Louis, Mo.; "Do the Sanitary Interests of the United States demand the Annexation of Cuba?" by Benjamin Lee, M.D., Secretary Pennsylvania State Board of Health, Philadelphia.; "Railway Sanitation," by Samuel W. Latta, M.D., Medical Examiner Pennsylvania Railroad Voluntary Relief Department, Trenton, N. J.

PUNISHED FOR MAKING AN INCORRECT DIAGNOSIS.—A surgeon of high rank in the French military service was recently retired on a pension because he had treated a soldier for mental disease who was in reality suffering from the results of a beating at the hands of one of his comrades.

SOME CHINESE DOCTORS.—Colonel Cheng-Ki-Tong, military attaché of the Chinese Embassy in Paris, has written several books to instruct the Western barbarian concerning the ways and customs of the inhabitants of the Flowery Kingdom. In one of them he relates some tales of medical practice in that land, the two following being noted by the *Medical Recorder:* A certain physician having advertised that he had an infallible remedy for curvature of the spine, a hunchback applied to him and asked if he could straighten his back. The doctor undertook to do so, and placed the unfortunate patient on his back on a flat board. He then placed a similar board on his chest and abdomen, and loaded it with heavy weights and stones. The result of this novel orthopedic surgery was that the patient was straightened out so effectually that he died on the spot. The quack claimed his fees on the ground that he had kept his promise; the bargain was that he should straighten his patient's back, but nothing had been said about his life! In China, it appears, the distinction between physicians and surgeons is more sharply defined than with us, and every man is expected to stick to his own branch of the profession. A rich merchant was struck by an arrow, which remained fixed in the wound. The principal surgeon of the place was sent for, and after insisting on pocketing his fee in advance cut off the projecting end of the arrow, leaving the point buried in the patient's body. On being asked to extract it, he said medical etiquette would not allow him to trespass on a brother practitioner's province; the arrow being inside the body, the case was clearly one for a physician!

SPONTANEOUS RUPTURE OF THE HEART.—Dr. Mallet, of Paris, described before the Société Anatomique of that city a case of this accident which occurred last May in the Hôpital Tenon. The patient was a man aged seventy-nine, with pulmonary disease. He died suddenly after rising to micturate. A rent, almost vertical and over two inches long, was discovered in the anterior aspect of the wall of the left ventricle. The pericardium was full of blood, the aorta atheromatous, and the left coronary artery nearly obliterated. All the valves were normal. Dr. Mallet quotes Odriozola's statistics of spontaneous rupture of the heart. That observer could only collect 176 authentic cases. In many instances the patient was old, being between sixty and seventy years of age in 36, and between seventy and eighty in 45. The accident appears most frequent in women. As a rule, the escape of blood into the pericardium is considerable. The rent in the wall was unusually large in Dr. Mallet's case. In nearly every instance in Odriozola's statistics the rupture was in the anterior part of the left ventricle. The original report of the case deserves study. The rupture apparently took place fifty-three hours before death, when the patient was seized with dyspnœa and epileptiform convulsions marked in the upper extremities; his face turned pale. The exertion of rising to micturate caused immediate death, probably by sudden escape of blood into the pericardium. A similar history has been recorded in other cases of spontaneous rupture of the heart.—*British Medical Journal.*

FORMULÆ FOR THE USE OF CREOLIN.—During the last few years none of the more recent remedies has had such a rapid success as creolin, identical with a patent fluid, of which a refined preparation has been named "Liquor Antisepticus." When creolin was suddenly recommended in Germany as an unsurpassed non-poisonous disinfectant, many voices were heard which objected to the use of a remedy that was a "patent article;" but the hesitation was soon overcome when it was found that the preparation really fully deserved the claims made for it. In many hospitals, clinics, and in private practice, creolin has completely superseded the use of corrosive sublimate, carbolic acid, iodoform, etc., in antiseptic surgery. Authorities like Von Nussbaum, Von Esmarch, Professor Fröhner, Dr. Kortum, have given such favorable verdicts on creolin that it has now become a generally used disinfectant—for instance, for sterilizing instruments before operations, for irrigation of wounds after operation. Creolin is especially convenient for the disinfection of the hands. In the ophthalmic, aural, and gynecological practice its use has become general. For prevention of the formation of pus, and for deodorizing large carcinomata, profusely discharging ulcers, creolin has proved very successful. The following are the daily formulæ in Germany (*The Provincial Medical Journal*):

*No. 1.—Solutio Creolin (half per cent.).*

℞. Creolin..... ♏ x.
Aquæ dest..... ʒ iv.

Sig.: To be shaken before use. For the irrigation of wounds, impregnation of tampons, moistening of bandages, etc. Also for washing the genitals, and for syringing the uterus and vagina after delivery.

*No. 2.—Solutio Creolin (two per cent.).*

℞. Creolin..... ʒ j.
Aquæ dest..... ʒ vj.

Sig.: To be well shaken before use. For the preparation of poultices and all dressings, for sloughing wounds, and for the disinfection of hands and instruments; also as a hæmostatic.

*No. 3.—Injectio Creolin.*

℞. Creolin..... ♏ ij. to x.
Aquæ dest.....ad ʒ iv.

Sig.: The injections. As an injection for gonorrhœa, leucorrhœa, and catarrh of the bladder.

*No. 4.—Pulv. Creolin.*

℞. Creolin..... ♏ xxv. to ʒ j.
Acid. boracic..... ʒ iij.

Sig: Antiseptic powder. For dry bandaging; for eczema in the neck or nose.

*No. 5.—Oleum Creolin.*

℞. Creolin ..... ♏ xv.
Olei olivæ..... ʒ ij.

M. Sig.: Antiseptic oil. For inunction of the hands in gynecological practice.

*No. 6.—Pilula Creolin.*

℞. Creolin..... ♈ xvij.
Extract. et pulv. glycyrrh.....ää q. s.

Make 100 pills. Coat with collodion. Sig.: Two pills to be taken night and morning.

*No. 7.—Ungt. Creolin.*

℞. Creolin..... ♏ xij.
Lanolin..... ʒ ss.
M. F. ungt.

CONJUGAL DIABETES.—Dr. Debove read a note at the Société Médicale des Hôpitaux on the coexistence of diabetes in the husband and in the wife. Of fifty cases of diabetes, Dr. Debove observed five which existed simultaneously in the husband and in the wife. The same coincidence was established by Dr. Lecorché, who thought that this coincidence can only be explained in two ways: by the use of the same defective alimentation, or by the cares of life shared in common by husband and wife. Dr. Debove said that he could not accept this explanation, as women, from the nature of their habits and the exigencies of their sex, do not live exactly as their husbands. Hence it

is that gouty couples are rare. He would therefore ask if diabetes were contagious; but for the present we must rest contented to register the fact. If new facts should show that conjugal diabetes is not a simple coincidence, it is only then one could propose a theory, which for the moment would be premature. Five or six other members also cited one or more cases in which they observed the coexistence of diabetes in the husband and wife.—Paris Correspondence of *The Lancet.*

Iodine in the Treatment of Warts.—According to Dr. Imossi, the tincture of iodine, given to adults in doses of ten drops twice daily, has proved very successful in preventing the further development of warts, and causing those already present to disappear. Dr. Imossi noticed, in the ten cases which had come under his observation, that the treatment produced striking emaciation, a fact which he has since turned to account in the treatment of obesity. He has thus succeeded in procuring a diminution of weight of about twelve pounds in three weeks.

Treatment of Gonorrhœal Rheumatism.—Dr. Buffet, of Elbeuf, has published some interesting observations on the course and treatment of gonorrhœal rheumatism, and concludes his paper with the following considerations: 1. Gonorrhœal rheumatism, often monoarticular, may affect several joints. 2. The small joints may be affected as well as the larger joints. 3. The malady may attack the tendinous sheaths, muscles, nerves, and cellular tissue. 4. The clinical difference with articular rheumatism consists in the absence of fever, of sweats, and in the fixity and the tenacity of the lesions. 5. The malady may terminate by anchylosis, suppuration, or by muscular atrophy. 6. The treatment reduces itself to placing the limbs in a good position, employing revulsion, massage, and electricity. The salicylate of soda and the anti-gonorrhœal medication have no action whatever.

Vaccinal Syphilis.—On August 6th last, Dr. Hervieux, director of the vaccination department at the Academy of Medicine, reported that five cases of vaccinal syphilis had come under his observation among the children that had been vaccinated at the Academy. The most minute inquiry could not discover the source of the accident, as the two subjects from which the vaccine lymph was taken were, to all appearances, perfectly healthy. Dr. Fournier, the well-known syphilographer, however, believed that he found in one of the subjects some induration of the epididymus and of the testicle, which would lead to the supposition of the existence of hereditary syphilis. The anti-vaccinators would, of course, try to make good capital out of this unfortunate, though happily extremely rare, circumstance, and would denounce the whole system of vaccination as being most dangerous to public health. But Dr. Hervieux, anticipating this, declared at the Academy that for the sake of a few regrettable cases vaccination, whether in man or animal, should not be condemned, when it is considered that millions of persons have been benefited by vaccination since its discovery by Jenner. A short time ago a few cases of suspected vaccinal syphilis occurred among some children who had been vaccinated at Motte-en-Bois, in the Department of the North. An inquiry was held, and Dr. Hervieux read the report at the last meeting of the Academy of Medicine of the result, from which it would appear that it was a false alarm, that nothing proved that the accidents or ulcerations which appeared on the children's arms were of a specific character. The appearance of the ulcerations eight or ten days after the vaccination would show that one was in presence of ordinary non-syphilitic accidents.

Deaf-mutism.—In a very interesting note by Dr. Baratoux (Paris) on deafness, the writer makes out that there exists more than 200,000 deaf-mutes spread all over the surface of the globe. For France, the proportion is 6.25 deaf-mutes per 10,000 inhabitants; and in 1880 the enlisting committee of the Department of the Seine had to reject sixty-seven young men affected with diseases of the ears, while only sixty were rejected for pulmonary phthisis, and sixty-five for diseases of the heart. It is lamentable to think, says the author, that more than half of the cases of deafness proceed from the negligence of the laws of hygiene, and can be easily prevented if proper measures be taken to remedy the morbid causes which prepare the deaf-mutes. It has been demonstrated that, notwithstanding certain statistics, deafness at birth is rare, that it represents at the most one-fourth of the total number of deaf-mutes. But it is in the early part of the life of the child that the deafness most frequently occurs, resulting from lesions more or less unperceived, and thus appears to be congenital. Deaf-mutism at birth is caused by consanguineous marriages, marriages between deaf-mutes, and certain fœtal malformations little known. Infantile deaf-mutism is caused by lesions which may be produced by the improper application of the forceps, nasal catarrh of the new-born babe, falls on the head, tight compression of the ear by a cap, exposure to cold, negligence of cleanliness, introduction of foreign bodies into the ear. Among the causes of deaf-mutism, heredity plays a rôle much less important than is generally supposed. The proof is that deaf-mutes almost always give birth to children who hear and speak well. The proportion rises a little when one of the parents is a deaf-mute and the other hears. Consanguineous marriages, which represent in France about two per cent. of marriages, produce about one-fifteenth of congenital deaf-mutism. Dr. Ladreit de Lacharrière, a well known aurist, has laid it down as an axiom that whenever a child loses its hearing during the first eight years of its existence, it becomes dumb by its forgetfulness of language, and until the age of four years this mutism is fatal.

Medicamentous Eruptions.—In his inaugural thesis for the doctorate, under the title of "Medicamentous Eruptions," Dr. Deschamps thus summarizes the common characters and the course of the eruptions which may follow the administration of a medicament. Among the medicaments the employment of which may determine erythematous eruptions the list is headed by copaiba, then follow belladonna, the sulphate of quinine, turpentine, stramonium, the protoiodide of mercury, the bromide of potassium, the syrup of poppies, the preparations of arsenic, etc. Those which produce vesiculous affections are the bromide of potassium, the alkaline iodides, cubebs, the santonate of soda. Those which give rise to pustulous affections are the iodides, arsenic, the bromide of potassium. The papulous affections are produced by Fowler's arsenical solution, by the hydrochlorate of morphia in hypodermic injections. Bullous affections are produced by copaiba and the sulphate of quinine. Hemorrhagic affections are produced by the sulphate of quinine and the iodide of potassium. It may be seen from the above enumeration that the same medicamentous substances may give rise to different cutaneous affections, whence it may be concluded that the effects which are always due to the same physiological procedure, viz., the elimination of the medicament by the skin, vary a good deal as regards the different forms of eruption, according to the aptitudes of receptivity of individual idiosyncrasies. It goes without saying that the treatment of these eruptions should consist in the momentary cessation, or at least in the diminution of the doses of the medicament, its suppression not being effected always without grave inconvenience.

Début of a Lady Professor.—Signorina Giuseppina Cattani recently read herself in as incumbent of the newly founded chair of bacteriology in the University of Bologna. The subject of her lecture was bacteriology in its relation to modern pathology. She was received with great applause. The learned lady is thirty-one years old, and has been assistant in the Bologna Pathological Institute since 1884.—*British Medical Journal.*

## Original Articles.

### KNOTS, LIGATURES, AND SUTURES.[1]

BY B. FARQUHAR CURTIS, M.D.,

ATTENDING SURGEON TO ST. LUKE'S HOSPITAL, NEW YORK.

IT is well, sometimes, to review the groundwork of our practice in order to see what advances have been made, what old ideas have proved worthy of being retained, and what old methods should be discarded; and this must be my excuse in presenting the trite and elementary subject here considered.

*Knots.*—The foundation of ligatures and sutures is, of course, the knot, and several forms of knots are used in surgery. It may seem to be scarcely worth while to emphasize the necessity of tying even a simple knot properly, and yet I have seen some good surgeons to whom it appeared to be more natural to tie a "granny-knot" than a square knot. If the knot is wrongly tied, it cannot be made strong by any number of additional turns. The best verbal rule for tying the square-, or reef-knot, is to pass the same end over the other in both turns; thus, if the end held in the right hand is passed over and turned around the end held in the left, it naturally passes into the left hand; and, in making the second turn, the same end (now held in the left hand) must be passed over and

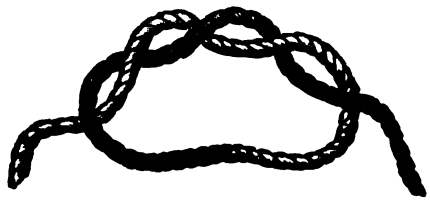

FIG. 1.—Surgeon's Knot.

around that held in the right. Thus the motion of the hands is reversed, and it is here that the tendency to error appears, for it is more natural to make the same motion of the hands in both turns. When there is much tension, as in bringing the edges of a widely gaping wound together, an extra twist is given to the strands in the first half of the knot, the second half being then tied as usual, and the same rule applying—to always pass the same strand over. This makes the surgeon's knot (Fig. 1). The extra twist simply keeps the first half of the knot from slipping while the second half is being tied. The surgeon's knot should never be used for ligatures, because it cannot be drawn tight enough; nor for tying sutures of fine silk, for the thread will break before the edges of the wound can be brought into contact.

When the tension is extreme, and a slippery catgut is used, it is well to tie a third turn after the square knot is completed, and the same rule must still be followed. This additional turn should always be employed in tying the surgeon's knot in catgut, for the double turn of the first twist does not correspond with the second turn made in the ordinary way. In tying knots there is one practical point which is not often enough insisted upon, namely, the greatest tension must always be exerted upon the first turn, for that is tied around tissues which are more or less elastic and yielding, and the encircling loop of thread helps to take up the extra strain, so that the material may be safely put to its fullest stretch. In the second turn, however, there is no such safeguard, and a pull which the thread bore well enough in the first turn will easily break it in the second.

Another knot which is sometimes useful in surgical work is the "clove-hitch" (Fig. 2), which is made by throwing two half hitches over any object. As it does not slip easily, it is employed for securing a catheter in the bladder; or for fastening a scarf upon a limb in order to get a good purchase for reducing a dislocation, or the deformity of a fracture. The "Staffordshire knot" will be considered later.

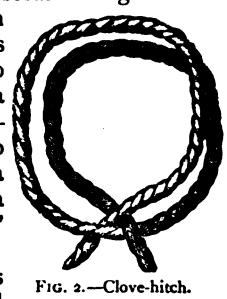

FIG. 2.—Clove-hitch.

*Ligatures.*—For ordinary ligatures the thread is merely passed around the vessel or stump of tissue to be ligated, and tied with a square knot. In ligating a thick pedicle when the tissues are very elastic, and a slippery catgut is used, the surgeon's knot may be employed, but, as a rule, it should not be used for ligatures. When a ligature is to be tied around a vessel, the points of the thumbs or of the fingers should be carried down the thread close to the knot, so as to make a direct pull upon the knot itself, and to avoid drawing the tissues out of place, or pulling the enclosed mass of tissues off, or at least displacing the artery-forceps. When a clamp or forceps has been applied to a large surface or mass of tissue, it is well to take it off after the first half of the knot is drawn tight, for then it can generally be drawn tighter before the second half is made. In the same way, if two or more artery-clamps have been applied close together, and it is desired to include them all in one ligature, it is best to take off the clamps one by one, as the first half of the knot is drawn up, at least until only one clamp is left. By adopting this method in all cases, a great deal of time can be saved, the assistant removing the clamp as the first half of the knot is tied, and being ready to cut the thread when the knot is completed.

When there is difficulty in securing a bleeding point on account of the friable nature of the tissues, or because the latter are too dense to be pinched up by the forceps or ligature, the hemorrhage can be arrested by passing a suture deeply underneath the bleeding vessel, and tying the thread so as to include it. It is thus that Horsley controls hemorrhage in his extensive operations upon the delicate tissue of the brain, where it is impossible to apply ligatures in the ordinary way. Before excising any part of the cerebral tissue, he surrounds it by a series of these deep suture-ligatures, and the operation is then practically bloodless. This method is greatly superior to the old one of tying under a tenaculum hooked under the bleeding point, or under a needle similarly placed and allowed to remain for some hours *in situ*.

When an artery is to be tied in its continuity, catgut is now almost exclusively employed for the ligature. It is not necessary to draw the thread tight enough to divide the internal coat of the artery (as used to be the rule), for the lumen of the vessel will be obliterated by simple adhesion of the internal surfaces. But if it is necessary to obtain a permanent obliteration of the vessel, it is wiser to apply two ligatures, and to divide the artery between them, for, with an aseptic course of the wound, there is so little new tissue and blood-clot formed that the vessel

[1] Read before the Surgical Section of the New York Academy of Medicine, October 14, 1889.

may become permeable again, even if the ligature has been applied tightly enough to divide the intima.

If a vein has received a small wound which can be picked up by forceps without entirely occluding the lumen of the vessel, a ligature can be thrown around the forceps, and these lateral ligatures have been frequently applied without destroying the permeability of the vein. This is, of course, a matter of great importance in those large veins which are almost the only channels for the return of the blood from a limb.

In tying off large pedicles of tumors, especially those which are to be dropped into the abdominal cavity, it is not safe to depend upon a ligature simply tied around the pedicle as a mass, and it is necessary to transfix the pedicle with the ligature before tying, and to tie it in two or more portions. In this way the ligature encircles a smaller mass, and, each loop being passed through the tissue of the pedicle itself, it is less likely to slip over the end. The thread is passed through the pedicle with some blunt instrument, such as an aneurism-needle, and it is well always to hold one end of the thread in the hand along with the handle of the needle, allowing the other to hang loose, so that, when the loop has been picked up from the needle and the latter withdrawn, the surgeon may be sure that the two threads are not twisted in each other. The loop is then cut, and the two halves of the thread are made to twist around each other, lest the pedicle should split at the point of puncture and hemorrhage occur where it would not be controlled by either ligature, and each thread is then tied around its half of the pedicle (Fig. 3). In tying the ligatures the greatest amount of compression will be obtained by placing the knot directly opposite the point of transfixion, and this is especially true of the broad, flat pedicles, in which, if the knot is properly placed, it will gather the comparatively thin, free edge of the pedicle toward the centre like a curtain. Instead of twisting the two threads, they may be tied together in a square knot at about the middle of their length, which is drawn firmly against the point of transfixion, and the two halves of the ligature tied as before.

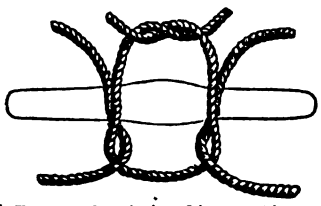

FIG. 3.—Interlacing Ligature (three loops).

Tait has introduced a very good method of applying ligatures to pedicles (called by him the "Staffordshire knot"), which combines all the advantages of the method just described, and requires less time to apply it. When the loop is picked up and the needle withdrawn, after transfixing the pedicle, the loop is drawn upon until it is large enough to slip over the tumor, then it is thrown over, so that it lies upon the same side as the free ends of the ligature. One of the ends is passed through the loop, and both ends are then drawn upon until the proper amount of constriction has been obtained, when they are secured by tying them across the loop in an ordinary square knot (Fig. 4). A somewhat similar ligature may be tied without drawing the loop out and passing it over the tumor, by throwing one of the free ends around one-half of the pedicle, passing it through the loop, and then tying it with the other end around the other half of the pedicle; but great care must be exercised in drawing the first half very tight before the second half of the pedicle is constricted, or there may be difficulty in drawing it sufficiently tight afterward.

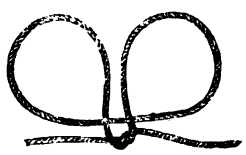

FIG. 4.—Staffordshire Knot.

A small pedicle may be transfixed with a single thread, which is first tied around one-half, and the ends then carried around the entire pedicle, and tied upon the other side. If the tissues of a pedicle are very resistant, it will be well to apply a clamp temporarily where the ligature is to be placed, and to tie the ligature in the groove made by the clamp. The best material for ligatures, for pedicles of any size, is undoubtedly silk, for catgut is too readily absorbed, and is too bulky when sufficiently thick to be strong; but some surgeons prefer catgut. The silk becomes incapsulated, and gives no trouble.

*Sutures, Interrupted and Continuous* (Fig. 5).—It s unnecessary to describe the interrupted and the continuous sutures, but a few words may be allowed as to which form is the better suited to any given case. Where there is much tension, the interrupted suture is to be preferred, for if it should yield in any place the integrity of the other stitches would not be impaired, whereas if one or more of the line of stitches in the continuous suture should break or cut out, the entire line would be slack. When very accurate apposition is desirable, as in wounds upon exposed parts of the body, the interrupted suture is also the better, for, with the continuous, one is apt to find on reaching the farther end that there is a surplus of material in one edge, especially if they were unequal to begin with. With the interrupted suture, on the other hand, even if one lip of the wound is longer than the other, by putting the first stitch in the middle and then halving the distance on each side with each succeeding stitch, the superfluous length of one side can be so evenly distributed that the inequality entirely disappears under the pressure of the dressing and in the process of healing. In using the continuous suture, it is well to have an assistant lift up a fold and make tension on both ends, so that the edges shall be evenly stretched; or, if no fold can be raised, he should hook a tenaculum in each end of the wound and thus make tension while the sutures are inserted.

FIG. 5.—Continuous Suture.

The great advantage of the continuous suture lies in the ease and rapidity with which it can be applied, and consequently it is to be employed for almost all other wounds than those just noted.

The continuous suture can be finished very neatly by taking the last stitch with the thread double (the free end of the thread being left long enough to remain in the stitch), and when the stitch has been pulled tight the free end of the thread on one side is tied with the needle-loop on the other. If the thread should be too short for this manœuvre, the loop of the last stitch is left long and tied (using the double thread as one strand) with the free end of the thread after the needle has been removed; or an interrupted suture may be put in with another thread, and one of its ends tied with the free end of the continuous suture.

*Glover's Suture* (Fig. 6).—An irregularity of the seam is often seen in the continuous suture, owing to the fact that, although the needle is passed at right angles to the incision at each stitch, there is an oblique pull upon the lips of the wound when the suture is finished, because the thread passes obliquely across the incision from one stitch to the next. This can be avoided by passing the needle after each stitch through the loop of the preceding one, thus making a sort of chain-stitch, called the "glover's suture," and making each stitch partially independent of the rest. This expedient allows of very accurate apposition, and is also useful when the tension upon the suture varies in different parts of the wound, for it enables one to keep the stitches tighter in one part than in another.

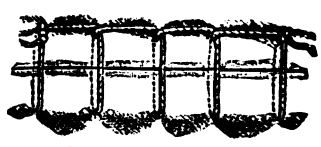

FIG. 6.—Glover's Suture.

*Mattress or Quilt Suture* (Fig. 7).—Another variety of the continuous suture is the mattress or quilt suture, although the latter may be so applied as to be rather a modification of the interrupted form. The mattress suture is designed to bring broad surfaces into apposition, the needle being passed in the ordinary way for the first stitch and the thread tied, but instead of carrying the needle over the wound, and introducing it in the same direction as be-

fore, it is inserted upon the same side as it emerged, and passed through both lips of the wound in the opposite direction. Thus the direction of the needle is reversed at each stitch, and the external loops of the stitches, instead of lying across the incision, lie upon the skin on each side of the latter, and parallel with it, as seen in the figure. It is evident that the same principle may be used as to passing the needle, but by cutting the external loops upon one side and leaving the ends long, each stitch can be tied as in the interrupted suture, care being taken not to tie so tightly as to cause sloughing. This suture has a tendency to cause great eversion of the edges of the wound, and this peculiarity makes it an excellent suture where the skin is thin (as in the eyelids or the scrotum), for here the skin has a natural tendency to inversion; and also when the skin is bound down by cicatricial tissue, as around old fistulæ. It is a capital suture for bringing the deeper parts of a wound in contact, as a sort of tension-suture, and has been especially recommended for this reason for the abdominal wound in laparotomy.

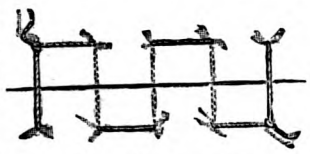

FIG. 7.—Mattress Suture.

*Cobbler's Suture* (Fig. 8).—Another variety of the continuous suture is the "cobbler's stitch." This is best applied by a needle set in a handle with an open eye near the point. The needle is passed through both lips of the wound, and one end of the thread caught and pulled through on the withdrawal of the needle. The thread is allowed to remain in the needle, and the latter is again passed through the lips of the wound for the second stitch, when the thread is removed from the eye and the other thread is caught up in its place and pulled through by withdrawing the needle. Thus both threads pass through

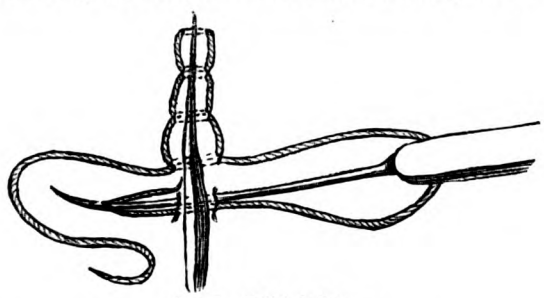

FIG. 8.—Cobbler's Suture.

each puncture of the needle, but in opposite directions. When the entire wound has been closed the ends of the thread are tied together. The external loops of the stitches form a continuous line on each side of the incision and parallel to it. Of course, the same suture could be made by a thread with a needle at each end, the needles being passed in opposite directions through the tissues at the same point; but one must be passed and its thread drawn tight before the other is introduced, for the second will probably pierce the thread of the first and prevent it from being drawn any tighter. This suture is very useful for covering in broad, oozing surfaces in pedicles which it is impossible to ligate *en masse*.

*Lead-plate Suture* (Fig. 9).—When there is great tension of the skin, or when there is a tendency of the deeper parts to fall away from each other and to leave a cavity, some deep sutures are passed at a distance from the edges of the wound to assist the ordinary sutures in closing the gap. Sutures of heavy catgut, or silk, or wire may be employed for this purpose, but most useful are the lead-plate sutures. The lead-plate suture consists of a wire with a lead plate about an inch in diameter fastened to each end, thus distributing the pressure over a considerable area of skin and permitting the wire to be drawn very tight. In placing these sutures, which are always passed at some distance from the wound, it is well to put a little of the iodoform or other gauze used in the dressing between the plate and the skin to lessen the danger of excoriation. The wire is secured to the lead plate by twisting it around little projections which are cut in the edge of the latter; or a perforated shot is slipped over the wire at each end, pressed against the plate, and clamped when the desired tension has been obtained; or

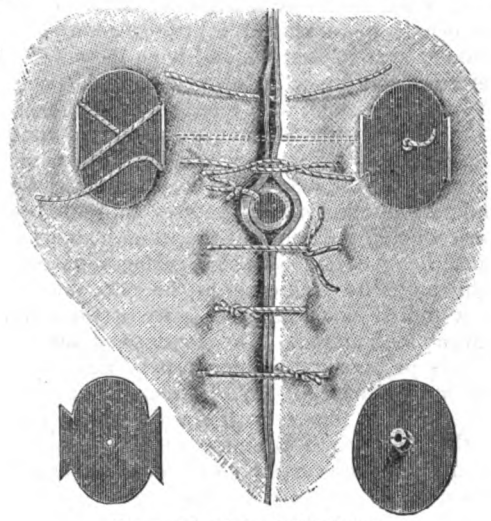

FIG. 9.—Lister's Lead-plate Suture.

the wire is passed through and twisted around a bead slipped over its end. An ordinary flat button can be used instead of the lead for the plates. Two of these lead-plate sutures will usually be found sufficient.

*Quill Suture* (Fig. 10).—The old quill suture has almost entirely disappeared from use, being replaced by these lead-plate sutures, and by the method of buried sutures; but in some cases it will still be found useful. The quill suture was employed where it was desired to get close apposition of broad surfaces, as in the old-fashioned operation for repair of a lacerated perineum. The necessary number of sutures are passed, the needle, carrying a double thread, being entered far from the edge of the wound and passed very deeply, as if for interrupted sutures. A quill, or a piece of rubber or glass drainage-tube is laid along each side of the wound where the threads emerge, the double threads of each suture are separated, passed on each side of the tube, and tied together over the latter. All the threads on one side of the wound are tied, then those on the other are drawn tight and secured over the other tube in the same manner.

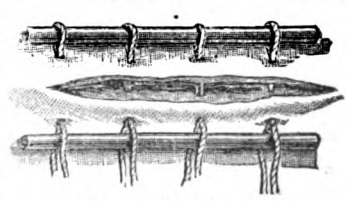

FIG. 10.—Quill Suture.

*Hare-lip Suture.*—Finally, we must notice the hare-lip or twisted suture, which consists of a pin passed through both edges of the wound, and a soft thread twisted around the projecting ends of the pin and across the edges of the wound, approximating the latter, and also pressing down the margins so as to prevent eversion. The ends of the pin are then cut off close to the threads. In three or four days the pins are withdrawn, being loosened from the threads by gentle rotation, and the latter are left for a few days longer adhering to the wound and holding it together. This method of closing wounds is especially adapted to cases in which the tension is great and there is a lack of support from underlying tissues, and it is most frequently employed in operations for hare-lip. In passing the pins through the lips they are entered half an inch or more away from the edge of the wound, and passed obliquely so as to issue on the raw surface of the wound, just avoiding the mucous membrane; then they are entered on the opposite raw surface at the same point, and made to issue from the skin at the same distance from the wound on the other side, so that nothing is exposed on the mucous membrane of the mouth. A few fine, interrupted sutures secure exact apposition of the skin and

the vermilion border of the lip, and it is well also to insert one of these where each pin is passed, removing the thread temporarily for the purpose.

*Buried Sutures.*—The formation of cavities may be prevented in wounds in another way—by the use of the buried suture. The buried suture is made with fine catgut and a curved needle, by picking up a little tissue on each side of the wound near its bottom, and tying the stitch. Then the operator picks up a little tissue with his needle on one side of the wound, and then on the other, keeping close to the angle at the bottom, and making a continuous suture, each stitch being drawn tight as soon as made. When one end of the wound has been reached, he turns back and adds another tier of sutures in the same way, each tier reducing the depth of the wound about half an inch, until the two raw opposing surfaces have been as thoroughly united to each other as the cloth upon the two sides of a quilted cloak, and the cavity of the wound has been entirely obliterated. The continuous suture is the best for this purpose, but in some cases interrupted sutures will answer instead. With thorough antisepsis it is sometimes possible to sew up the entire cavity of an abscess in this way without drainage, after clearing the walls of granulations by the curette, and to obtain primary union. The buried suture is most useful in plastic operations for lacerated perineum, or after excision of anal fistula.

*Wire Sutures.*—When wire is used for sutures it is introduced by a strong needle with a large eye; or a needle is threaded with both ends of a stout silk thread, and the end of the wire is sharply bent and hooked into the loop thus formed, by which it is drawn through the tissues. Wire sutures are secured by twisting, and forceps are generally used for this purpose, a "shield" (an instrument with a slot in it like a tongue-tie) being slipped down over the ends so as to compel the twisting to begin near the wound. When the proper tension has been obtained by twisting, a couple of tenacula are hooked under the loop of wire, and by drawing them apart the wire is bent at a right angle where it enters the tissues, and the external loop is made to lie smoothly on the surface. This is technically called "shouldering."

*Suture of Tendons.*—Tendons are sutured, primarily, in some wound; or, secondarily, after the original wound has healed, or after subcutaneous rupture. In the first case the wound is already present, and at most only requires to be enlarged in order to reach the tendon. In the second, the surgeon has a choice as to the wound, and in such cases the best means of gaining access to the tendon is undoubtedly by a curved incision, parallel to the course of the tendon, marking out a flap, with its base lying over the latter. When the tendon has been united and the flap returned to its proper position, the line of the incision will not lie directly over the tendon, and there will be less danger of cicatricial adhesions forming between the latter and the skin. When the tendon has retracted into its sheath, it is not wise to try to drag the ends down by forceps, for that is liable to lacerate them and to carry infection up into the sheath. The better plan is to open the sheath by a lateral incision as far as the end has retracted, for a few sutures will close the wound, and as it is placed upon the side it will be out of the direct line of tension, and even if immediate union is not secured, there will still be synovial membrane between the tendon and the tissues above it.

The most difficult part of the operation is the suture of the divided ends of the tendon, for the tension is often very great, in spite of all the relaxation that can be obtained by placing the limb in the most favorable position, and the tissue is so easily split by the thread that the tissues tear out. Some have employed a sort of quilt suture, made as follows: A thread is provided with a needle at each end, the ends of the tendon are made to overlap for about a quarter of an inch, and the needles are passed through both ends at once, from below upward, one near each edge of the tendon. When the stitch is drawn tight the loop of the thread forms a transverse suture on the lower surface, and the two ends are tied together across the upper (Fig. 11). When the two ends of the tendon cannot be made to overlap, a modification of this suture can be used. In this case the two needles are passed through one end from above downward, one near each edge, and then they are passed through the other end in the reverse

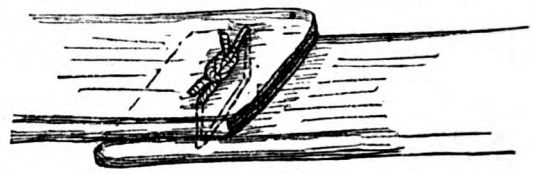

FIG. 11.—Suture of Tendon.

direction, from below upward, and the knot made across the upper surface of the latter end, holding the cut surfaces of the ends in close contact (Fig. 12). Of course both of these forms of suture can be made with a single needle, by beginning and ending the stitch where the knot is to be tied, and taking care to pass the needle in the proper direction at each puncture. This quilt suture answers very well for broad, flat tendons, but is altogether inapplicable to the small, round variety, which barely give holding ground for one thread. A theoretical objection of doubtful weight is the danger of cutting off the blood-supply of the ends.

But the greatest advances have been made in the suture of tendons since the proposition of Nicalodoni, to relieve tension by passing acupressure needles through the tendons above and below the point of division, suggested to Witzel the more practical idea of accomplishing the same object by relaxing sutures inserted in the ends of the ten-

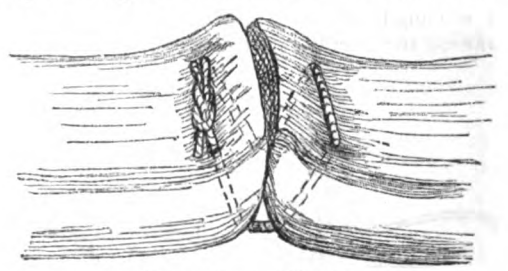

FIG. 12.—Suture of Tendon.

don in the wound (Volkmann's *Samml. klin. Vorträge*, No. 291). He passes a stout catgut thread through each of the divided ends, about half an inch away from the point of division, thus making a loop in each end which serves to hold them in apposition during the operation. Delicate catgut sutures inserted at the point of division are sufficient to insure contact of the divided ends, and the relaxing loops are then tied together across the point of division, thus relieving the fine sutures of all strain, for the heavier sutures are passed so far back that they are not likely to tear out. If a tendon has been divided close to its insertion into a bone, the distal relaxing suture is passed through the periosteum of the bone near the point of attachment of the tendon, and then the sutures are inserted in the same way.

*Suture of Nerves.*—It is to the French surgeons of the early part of this century that we owe the clinical demonstration that suture of nerves could be practised without danger of tetanus from "irritation," and with the growing proof that tetanus is due to a specific infection all fears of the procedure have disappeared, leaving us free to adopt bolder and securer methods of applying the sutures. At first the only suture considered allowable was the "paraneurotic," which included only the sheath of the nerve, with a portion of the surrounding cellular tissue. In most cases accurate adaptation of the ends of the nerve cannot be obtained by such sutures. The obstacle to successful suture of nerves, however, lies not so much in the mechanical difficulties as in the degenerative changes which are at once set up in both ends when a nerve has been divided, so that even with immediate restoration of phy-

sical continuity, functional restoration is delayed until the nervous tissue can be regenerated. It is true that some recent cases seem to show that immediate functional restoration is sometimes possible, but the evidence is not yet conclusive, and for most cases, at any rate, the older theory holds good. In fact, the functional results of secondary nerve-suture have been almost as good as when the ends have been immediately united.

If the ends of the nerve can be brought together so that the raw surfaces of the recently wounded nerve, or its freshened ends if the operation is secondary, are in contact, a simple suture or two of fine catgut will generally suffice; but if there is much tension, a quilt suture similar to that used for tendons may be employed, and perhaps relaxing sutures would be of advantage here also. But the true nervous tissue must be in contact, so that it will not answer to have the ends overlap. Nerves do not retract much when divided, but the operation is so often undertaken secondarily, when the ends of the divided nerve have degenerated into fibrous tissue, that it is necessary to remove a considerable portion before any real nervous tissue can be found, and thus a considerable gap is made. Various means have been adopted to overcome this difficulty, such as grafting the nerve into some neighboring nerve; cutting a flap from each end with its base toward the point of division, turning them into the gap and uniting them; replacing the lost tissue with fibres of catgut, decalcified bone, or even rubber drainage-tubes; transplanting into the interval portions of another nerve, or of a nerve from some animal; or even shortening a limb by resecting its bones so as to bring the separated ends together. But the simplest and best expedient is to stretch both ends of the nerve, and this will serve for most cases; for a nerve will bear a considerable amount of stretching without losing its functional powers, and even if a temporary suspension of these were caused, the final result would not be affected. A gap of an inch in the median nerve, for example, has been easily overcome by stretching.

*Suture of Veins and Arteries.*—Longitudinal wounds of veins have frequently been united by suture without occluding the vessel. Horoch (*Allgem. Wien. med. Ztg.*, 1888, 263, 279) has lately reported some experiments upon animals which prove that veins may also be circularly sutured after complete division, with preservation of the lumen, and that longitudinal and circular suture (after complete division) can even be applied to arteries; but the artery becomes gradually occluded by endothelial growth. Since the establishment of the fact that a clamp forceps can be applied laterally in case of wound of a vein, and removed in a few hours without secondary hemorrhage, so that the calibre of the vessel can be preserved, it has become unnecessary to suture the wound, and even the lateral ligature is falling into disuse. But circular suture, if it can be accomplished in man with preservation of the lumen of the vessel, would offer a new and welcome escape from the ligature of veins when the collaterals are insufficient. Suture of the arteries would also be useful, in spite of the fact that the vessel remains permeable only a short time, in cases where it was desirable to give the collateral circulation more time than usual to develop. I believe that the crewel needle, to be described below, would be excellent for the suture of vessels which were not so deeply placed as to make the use of a curved needle imperative, a double thread of fine silk being used which would completely fill the needle punctures and prevent oozing.

*Suture of Intestine and Stomach.*—The only available forms of suture for the intestine and stomach are those which bring the peritoneal surfaces together, for only in this way can union be obtained quickly enough to prevent leakage of the contents. This requirement is most simply fulfilled by the Lembert stitch, whether applied as an interrupted or continuous suture. The Lembert stitch is made by entering the needle about three-sixteenths of an inch from the margin of the wound, picking up the serous and muscular coats only, and leaving the mucous membrane untouched, and bringing the needle out about one-sixteenth of an inch from the edge. The needle is then made to pick up the serous and muscular coats on the other side of the wound, being entered one-sixteenth of an inch from the margin, and made to issue three-sixteenths of an inch from it (Fig. 13). On tying the two ends of the thread, the edges of the wound will be rolled in, and the two strips of peritoneum, about one-eighth of an inch wide, under which the stitch passes on each side, will be brought into contact (Figs. 14 and 15). After one line of such sutures has been inserted around the wound, a second is often advisable, which will turn in still more of the peritoneum and give additional security.

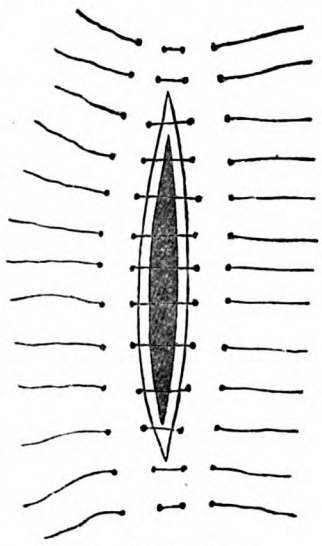

FIG. 13.—Lembert Suture.

In the dog's intestine the submucous coat is developed into a strong aponeurosis (first pointed out, so far as I know, by the simultaneous papers of Halstead and myself, *American Journal of the Medical Sciences*, October, 1887, although it must have been known to all experimenters), and if the point of the needle is made to scrape over the surface of this membrane so as to pick up some of its fibres, the stitch holds much more strongly than

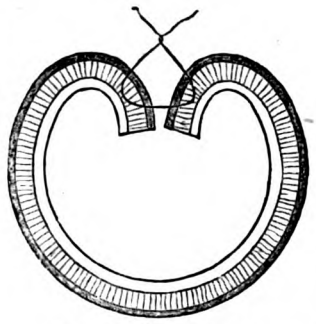

FIG. 14.—Lembert Suture.

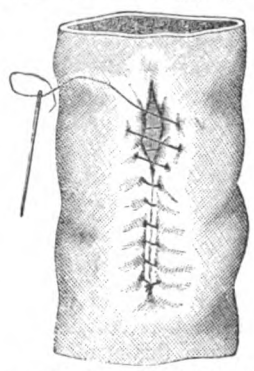

FIG. 15.—Continuous Lembert Suture.

when only the brittle and soft serous and muscular coats are included. But in man, where the submucous coat is mere soft cellular tissue, the stitches will not bear any very great strain, and it is difficult to pass them without wounding the mucous membrane. (Greig Smith writes as if the submucous coat were also fibrous in man, but this is not the case.) In general, the interrupted suture is to be preferred in intestinal work, for there is great danger that the continuous suture would be loosened by the premature cutting out of one of its links; but the latter is useful for the second (re-enforcing) line of sutures, as it requires less time to apply it.

One of the greatest difficulties in circular suture of the intestine, is the treatment of the mesenteric attachment at the wound. It requires great care to cover the raw surfaces here with the ordinary Lembert suture, even when the two peritoneal layers of the mesentery have been fastened together by a stitch at the wound, and a passageway of non-serous surfaces is very apt to be left in the wound communicating at one end with the interior of the bowel, and at the other with the fatty cellular interspace between the two layers of the mesentery. This forms an easy route for infection, and it is here that the suture most frequently gives way.[1]

[1] In a series of experiments upon dogs (loc. cit.), I used a rather

Senn has lately revived the old idea of protecting the line of sutures with a strip of the omentum stitched around outside, and claims good results.

The best needles for use in intestinal work which I have been able to find, are the fine needles with long eyes that are used by ladies for embroidering in crewels. They can be obtained from an inch and a half to an inch and three-quarters long. They carry a very large thread in proportion to their size, and are much more easily threaded than the cambric needle, or the milliner's needle recommended by Halstead. A straight needle held in the fingers is far better than a curved needle, which requires forceps, except in some situations where the sutures have to be applied to a wound deep in the abdomen. For such cases the slender curved needles of Schramm, or the Hagedorn intestinal needles, can be used, the latter having the advantage in the size of their eyes. Fine silk is the best material to employ in suturing the intestine and stomach, for catgut of the same strength would have a greater bulk, and necessitate a larger needle; moreover, catgut is difficult to obtain, while silk can be had anywhere, and soon sterilized by boiling. As the silk becomes encapsulated in serous exudation, it remains harmless.

More complicated methods of suture are in favor with some surgeons. The edges of the mucous membrane are

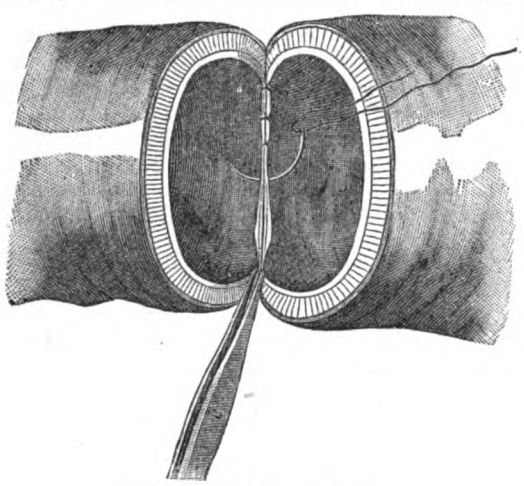

FIG. 16.—Wölfler's Internal Suture.

frequently united with a line of sutures before applying the Lembert stitches outside, and in operations upon the stomach this is advantageous, to protect the raw edges of the inverted wound from the action of the gastric juice. But in the intestine it seems to be an unnecessary refinement, except, perhaps, for a short distance at the mesenteric border. The Czerny suture is of this kind, and the Gussenbauer, as well as the suture advocated by Wölfler, shown in Fig. 16. In the latter about three-fourths of the sutures are tied with the knot free in the lumen of the bowel, but the rest must be tied with the knot outside, where it lies in the wound between the submucous and mucous coats. Halstead recommends a quilt suture, made by taking a Lembert stitch as usual, and then making another about one-twelfth of an inch from the first, but in the opposite direction, so that the end of the thread is brought out again upon the same side of the wound as it started from, and the two ends are tied there. The disadvantage of this suture is, that instead of turning in the broad surface of peritoneum under which the thread passes, as the Lembert stitch does, it turns in only the narrow strip along the edge of the wound which has been left free from sutures. The stitch, however, is not likely to tear out, and the first objection could be overcome by inserting a second line of sutures, if the prolongation of the operation were not considered an objection.

*Intestinal Anastomosis.*—A very great advance in intestinal surgery has been made by the proposition of Senn (*Annals of Surgery*, vii., 1888), to employ perforated plates of decalcified bone when it is desired to make an anastomotic connection between two adjacent loops of

FIG. 17.—Inserting the Ring.

bowel, instead of the tedious operation of uniting the edges of the openings in the two loops to each other by sutures. The plates have a large opening in the centre to allow the contents of the intestine to pass while they remain in place. One is passed into the opening in each loop, and the two are then tied together by the silk threads attached to them, and hold the edges of the openings in contact. Abbe has suggested (*New York Medical Journal*, March 23, 1889) oval rings of catgut, the latter being coiled until it is about of the thickness of a lead-pencil, and then flattened by pressure between two pieces of glass, for the decalcified bone plates are difficult and tedious to prepare, especially the large sizes, and the opening in them is in some danger of being too small. Brokaw, of St. Louis (*Weekly Medical Review*, August 17, 1889), has experimented successfully on dogs, with rings made of short pieces of rubber tubing threaded on catgut strands, to which the silk threads are attached. The method of application is in all cases the same. Each ring has six silk threads attached to it, one at each end and two on each side, each provided with its own needle. An incision is made in the bowel at the desired place, and the ring with its needles having been spread out upon a towel near by, the operator passes one of the end needles through the wall of the gut from within outward, about one-fourth of an inch from the end of the incision. The ring is then inserted into the bowel through the wound and the thread drawn tight; the other end can then be passed through the bowel at the point which corresponds to its attachment to the ring. With these two

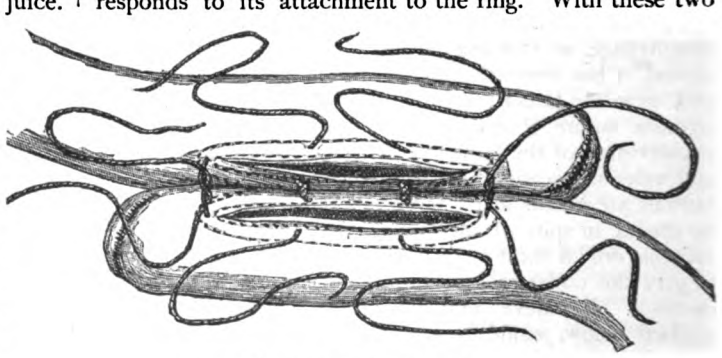

FIG. 18.—Tying the Threads.

threads drawn tight, the rest are easily passed at exactly the proper points (Fig. 17). The other ring is then inserted into the other loop of the intestine in the same way, and while an assistant holds the loops of the gut and the rings (easily felt through their walls) in apposition, the six pairs of threads are tied together (Fig. 18), but care must be taken not to exert so much force as to break the thread. Should one of the threads break, a needle armed with a thread which has a large knot on its end, can be passed through the ring and the wall of the bowel, so that the knot will catch in the former, in place of the broken thread. Half

complicated but reliable method of suturing this point, but it is unfortunately not often applicable to the human bowel, because the interstitial fat in the mesentery extends so far, not being limited to a little triangular interval near the intestine, as it is in dogs.

a dozen Lembert sutures are placed around the anastomosis, to diminish the strain on the rings, and to secure closer apposition of the serous surfaces. The operation requires only about fifteen minutes, and the rings can be applied in situations which would be inaccessible to ordinary sutures. (Fig. 19 shows a section through the opening and the rings *in situ*.)

This method is also applicable to the formation of a fistula between the stomach and bowel. But perhaps the most important development of the use of the rings is

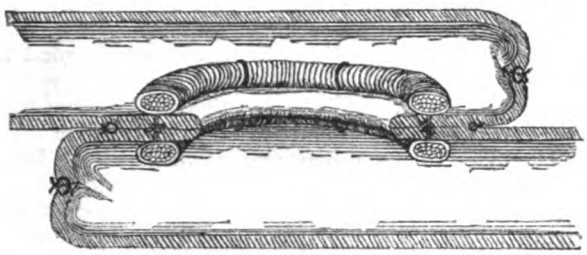

FIG. 19.—Section through Opening and Rings, in the Long Axis of the Bowel.

their use instead of circular suture of the intestine. In such cases the two ends of the divided bowel are closed by turning in the edges and uniting them by a continuous Lembert suture, which only takes a few minutes. Then the ends are made to overlap, slits cut in the side of each about an inch from the end, and the rings applied. The entire proceeding requires less than half an hour, and gives a much safer union of the two ends than the most skilfully applied intestinal suture, and if the rings and openings are made sufficiently large the functional results are just as good. A considerable number of cases are now on record in which the rings have been used successfully for entero-enterostomy, gastro-enterostomy, and as a substitute for circular suture of the bowel.

*Gastrostomy.*—We must mention here a very ingenious suture introduced by Greig Smith ("Abdominal Surgery," London, 1888) for securing the stomach to the abdominal wall for gastrostomy, and available also for securing any cyst to the abdominal wall for drainage (Figs. 20 and 21).

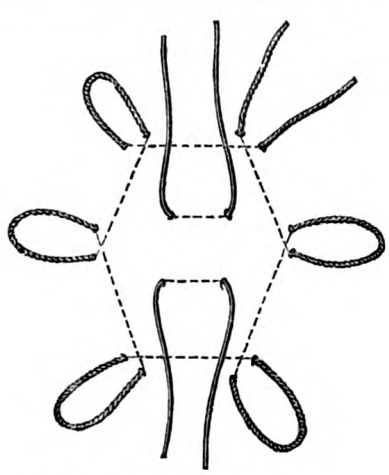

FIG. 20.—Fixation for Gastrostomy.

Having passed two wire sutures in the wall of the stomach, without penetrating the mucous membrane, and using it to steady that organ, he takes six long stitches in the wall of the stomach, surrounding the wire suture, passing the needle under the serous and muscular coats only, and including a hexagonal space large enough to contain the required opening. Each stitch is about half an inch long, and the needle is entered for the next stitch close to where it emerged from the last, leaving a loop four inches long hanging between the two. The abdominal wound is then partly closed to reduce it to the proper size for the fistula, and the peritoneum and skin are sewed together around the edges so as to cover in the raw edges of the remainder. While the wire suture holds the stomach against the wound, the other loops are picked up in turn by a needle set in a handle with an open eye at its point (like the needle in Fig. 8), inserted through the entire thickness of the abdominal wall from without inward at corresponding points, so that the six loops are drawn outside and lie upon the skin of the abdomen. A drainage-tube is then passed through the loops and coiled in a ring around the wound, the loops are drawn tight in succession, and the last one (consisting of the two free ends of the thread) is then tied over the tube. The wire sutures are also twisted over the tube, for they are useful subsequently in opening the stomach. In a case of gastrostomy in which I tried this suture it answered very well, but instead of the needle on a handle, I found it more convenient to use a large curved needle with a carrying thread of coarse silk, by which the loops attached to the stomach were drawn through the abdominal wall by passing the needle from within outward. I also found it very difficult to draw the thread of the loops even and tight after they had been passed over the drainage-tube, so I cut each loop and tied the ends together over the tube.

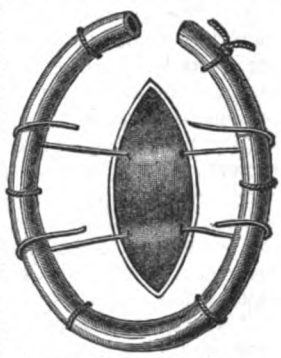

FIG. 21.—Gastrostomy, Fixation Suture.

*The Abdominal Wound in Laparotomy.*—The greatest difference exists in the methods adopted by surgeons in closing the abdominal wound made in laparotomy. All are agreed upon the necessity of bringing peritoneal surfaces in contact, but some surgeons use only a single row of sutures passing through all the layers of the abdominal wall, while others apply several series, uniting each layer independently. For small simple wounds, where the edges have not been exposed to much stretching or contusion, the simplest method will save time and will give perfect results, if care is taken to insert the sutures properly. In closing the wound in this way, a coarse silk is to be preferred (although silver wire, silkworm gut, or even a heavy, hard catgut may be used), introduced with a large straight needle. The edges of the wound are kept upon the stretch so as to prevent uneven retraction or protrusion of any of the various layers, and the needle is inserted about half an inch from the margin of the wound and carried obliquely toward it, so as to emerge upon the serous surface only one-eighth of an inch from the edge; it is then passed through the other lip of the wound at a point exactly opposite, in a reverse direction. Some surgeons use a thread with a needle at each end, and pass both ends of the suture from within outward. In tying the sutures, which are placed one-third of an inch apart, care must be taken to see that the serous surfaces are really brought in contact, but too broad a strip of peritoneum must not be turned up into the line of the wound, for it might become interposed between the tendinous and muscular structures, prevent their union, and result in hernia.

When several tiers of sutures are employed, the peritoneum is united with a fine thread and continuous suture for the whole extent of the wound. The transversalis fascia must be included in this stitch when there is much tension, or the suture will tear out. Then the tendon or muscle is secured by a second tier of stitches, made with a stout thread, and finally the integument is united over all. It is very advantageous to make a separate suture of the peritoneum, except in the simple wounds mentioned above, for if any septic trouble arises in the wound, the early and accurate union of the peritoneum shuts it off from the abdominal cavity. But the majority of operators make only two tiers of sutures, one for the peritoneum and one for the skin and muscular layers together, and this seems the most common-sense practice. Sometimes it may be necessary to use lead-plate relaxing sutures when the tension is great, but such cases seldom occur except in laparotomy for intestinal obstruction.

*Artificial Anus.*—In performing lumbar colotomy, it is well to draw the bowel into the wound and secure it to the skin around the entire incision before opening it, if it be possible to do so, in order to cover in the exposed surfaces and to shield them from infection. In making an artificial anus elsewhere, the peritoneum is drawn out of the wound with artery-clamps and sutured to the skin, so as to cover the raw surfaces here also, and the intestine is then drawn out of the wound and secured in the method preferred by the operator—a loop being drawn out and fastened by a few sutures to the skin, or by passing a rod or some other object through the mesentery; or by stitching the lips of the wound together in the middle with the mesentery between them, so that the central portion of the loop rests upon a bridge of skin. Or the presenting bowel is left inside of the abdomen, and simply secured to the wound by a circular suture, or several interrupted sutures. A method similar to that just described for gastrostomy might also be employed.

*Fixation of Abdominal Organs.*—When any of the organs in the abdomen become displaced or too freely movable, such as the kidney, spleen, or a lobe of the liver, they may be secured by sutures, and the same method has been employed for correcting malpositions of the uterus. The suture is in these cases of some coarse material, passed so as to include the capsule and more or less of the tissue of the organ, lest it should cut out. In all cases except fixation of the uterus, it has been found advisable not to depend merely upon the suture, but to tampon the wound, and thus secure an anchoring of the organ to a mass of cicatricial tissue embedded in the abdominal wall. In securing the uterus, after it has been restored to its proper position through a small wound just above the pubes, it may be stitched by separate sutures to the inner surface of the abdominal wall, or the sutures which close the abdominal wound (silk, or wire) may be made to pass through the fundus also, and to hold it up against the inner aspect of the wound.

Any organ or cyst may be secured to the abdominal wall by a couple of sutures, in order to evacuate the contents of an abscess or cyst through the wound. Some prefer a ring of sutures of fine material, but in the case of solid organs (liver, spleen) two deep sutures will answer. For some cases Greig Smith's suture for gastrostomy might be used. If the sutures hold well it will not be necessary to wait for adhesions to form. I recently evacuated an abscess of the liver through the pleural cavity by resecting a portion of the tenth rib, sewing the two layers of the pleura together as they lay in contact (but not adherent) over the diaphragm, making a circle of continuous sutures, and immediately opening the abscess through the diaphragm by an incision in the centre of the ring. No pus and no air entered the pleural cavity.

*Suture of the Bladder.*—Since the revival of the suprapubic operation upon the bladder, many surgeons have been studying the best method of closing the wound in that organ. Where the walls of the bladder are covered with peritoneum, a Lembert suture will secure union as in any other peritoneal wound, and wounds of the bladder have often been closed in that way; hence one bold surgeon has even suggested that every cystotomy should be performed intra-peritoneally, so that primary union could be obtained—a suggestion which is not likely to obtain favor, for the results of the ordinary operation are too good, even if an occasional fistula does prove obstinate. It is necessary, in the first place, that none of the material used for suture should project into the bladder, for it forms a nucleus for stone formation, and even catgut cannot be used in this way. Von Antal suggested (*Centralbl. f. Chir.*, 1885, 297) to bevel the edges of extra-peritoneal wounds of the bladder externally, so as to increase the extent of surface which could be brought together by sutures, as is often done in vesico-vaginal fistula, for instance. Brenner (*Arch. f. Chir.*, xxxv., 33) has lately recommended a suture passed around the wound in the bladder like a purse string, so as to pucker it up when drawn tight. Two sutures are employed, one being passed in the submucous layer, and one in the muscular, each about one eighth of an inch from the edge of the wound. The inner one is tied first, the mucous membrane being turned up into the wound, so that epithelial surfaces are everywhere in contact; then the muscular suture is tightened over that. In experiments on animals he has obtained excellent results. The usual method is to unite the wound in a linear manner, with fine thread and continuous or interrupted sutures, passed so as not to include the mucous membrane. But it is very exceptional to obtain complete primary union, although partial union is sometimes secured, and the sutures always do good by preventing the exit of the urine for a couple of days, and by that time the wound is granulating and the danger of urinary infiltration has been reduced to a minimum.

In speaking of the urinary organs we must not forget that brilliant results have recently been obtained in suturing the male urethra after rupture, or after resection of a strictured part. Successful cases of transplantation of skin or mucous membrane in the place of the excised tissue have also been reported. The material used for the sutures has been fine silk or catgut, but there are no special technical points to be noted in their insertion.

*Cæsarean Section.*—One more peculiar problem in abdominal work remains to be described, and that is the treatment of the uterine wound in the Cæsarean section, the successful solution of which by Sänger has resulted in restoring that old operation to favor instead of the mutilating Porro and Müller operations. The advance lay in applying the principle of the Lembert stitch here also, and the most approved method at the present day is but little more than an ordinary Lembert suture. A row of sutures is passed first, including all the tissues except the mucous membrane, the peritoneum being inverted into the incision when the knots are tied. A second is then passed, picking up only the peritoneum, which can be made to slide over the subjacent tissues and to cover in the first line of sutures. Primary union is easily obtained by this method.

NOTE.—Figs. 1, 2, 5, 6, 7, 9, 10, 14, 15, and 16 are taken from Esmarch's "Handbook of Surgery" (translated from the third German edition by B. F. Curtis, M.D.); and Figs. 3, 13, 20, and 21 are from J. Greig Smith's "Abdominal Surgery."

---

## APPARENT CANCEROUS TRANSFORMATION OF SYPHILOMA OF THE TONGUE—EXCISION OF THE TONGUE BY THE GALVANO-CAUTERY.[1]

BY G. FRANK LYDSTON, M.D.,

LECTURER ON GENITO-URINARY DISEASES IN THE COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO, ILL.

THE possibility of the existence of a combination of syphilis and carcinoma has recently attracted some attention from the profession, and it has been claimed in certain quarters that a transformation of a syphilitic into a cancerous process is possible. The first cases of combined cancer and syphilis were reported by Jonathan Hutchinson, and following him Langenbeck directed attention to this unusual class of cases. Lang, of Vienna, recently exhibited a case of the kind before the "Medizinisches Doctoren Collegium." The patient was a woman who had suffered from syphilis for a protracted period. Scars of former syphilitic processes were present upon the trunk and face, the palate being perforated, and the upper lip having suffered considerable loss of substance. At the time she came under Lang's observation, most of the ulcers were covered with a white scab, the histological examination of which did not reveal any sign of importance from a diagnostic standpoint. About a month later, however, a small, white, indolent ulceration appeared upon

[1] Read before the Mississippi Valley Medical Association, September 10, 1889.

the hard palate. A small portion of the involved tissue was excised, and upon microscopical examination by Professor Weichselbaum, was found to be epithelioma. In the course of the discussion Professor Lang stated that he had observed three other cases which were very similar, the development of the carcinoma upon a syphilitic soil being demonstrated in each instance by microscopical examination. The first case, which came under his observation in 1883, had suffered from a characteristic course of syphilis, which included numerous relapses of iritis and gummatous ulcerations upon the face. Under anti-syphilitic measures all of the ulcerations cicatrized, with the exception of one, which became transformed into a cancroid of the skin.

The second case was that of a man, aged forty-six, who had suffered from various syphilitic ulcerations on different parts of the face and body. After anti-syphilitic treatment one ulcer, located beneath the tongue, proved resistant to treatment, and became transformed into cancer. In the third case a syphilitic infiltration, located in the lower lip, underwent a relapse at the end of a year, and assumed a carcinomatous character.

It is unfortunate that the profession have not more carefully noted the cases in which carcinoma has developed upon a syphilitic base. There are many cases in which careful study might demonstrate the casual relation of syphilis to malignant disease.

The case which I have had the opportunity of observing, and here recording, was one the progress of which I had been enabled to study for a protracted period, and there can be no possibility of doubt as to the primary condition upon which the malignant disease that eventually destroyed the patient's life was engrafted. In recognizing the transformation of syphilitic processes into cancer, I do not wish to be understood as claiming that the histological elements of syphilis may be transformed into those characteristic of cancer, but that the elements of syphilis having been removed, they leave the tissue so damaged that continued irritation will result in cancerous degeneration. On the other hand, a syphilitic process may recur so frequently, and be so obstinate to treatment, that the irritation thereby produced is capable of causing cancer.

It is as yet too soon for us to discuss the question of the existence of special bacilli in syphilis and cancer for the purpose of disproving the possibility of the transformation of the one into the other. It is conceivable that both cancerous and syphilitic deposits may act in the same manner as other irritating processes in the tissues. It is to be presumed that if a cancer were present in the mouth of a syphilitic subject, syphilitic processes would be more apt to develop in the vicinity of the malignant disease than elsewhere. A somewhat similar relation exists between the presence of the syphilitic process and the development of carcinoma. Whether actual transformation can occur or not, it is certain that cancer may develop in tissues which are indubitably affected by a syphilitic process, and that said cancer may go on to destruction of tissue, and finally, of the life of the patient. This may occur without any preliminary change in the physical appearance of the tissues affected by syphilis prior to the development of the cancer. I feel warranted in speaking thus positively from my experience with a case which I am about to relate.

In regard to the bacillus of cancer, it is as yet an unknown quantity. As far as the bacillus of syphilis is concerned, no one has, so far, been able to positively demonstrate that the supposed bacillus of syphilis is really the specific bacillus. In the words of Dr. N. Senn, "that syphilis is a specific disease cannot be doubted, that it is due to a microbe cannot be doubted, but to establish this positively, experimenters must do what Koch did before he announced the specific origin of tuberculosis."

To put the matter of the transformation of syphilis into cancer concisely, I would say that I do not believe that syphilitic cells can possibly be transformed into cancer cells; but I infer that the irritation of the tissues produced by the former may, in the presence of favorable constitutional and local conditions, develop a new process of tissue-building or neoplastic formation which will result in the formation of cancer cells. I have taken the liberty of relating my own case in detail.

Case.—The patient, a man, aged twenty-nine, contracted syphilis at the age of eighteen. He stated that at that time he contracted a hard chancre, which inflamed and caused paraphimosis, which lasted about a month, and left the mucous membrane of the penis in an irritable condition that resulted in the frequent appearance of fissures and ulcerations, some of which were treated by me from time to time after he came under my care. Secondary symptoms appeared about four months after the primary sore, and according to the description a pronounced papulo-pustular eruption appeared and resulted in considerable scarring of the skin. Mucous patches presented themselves in successive groups, and, as the patient expressed it, "were very annoying, especially those upon the tongue." After the secondary period became manifest the physician in charge of the patient put him upon mercury, a thorough course of which was given for about three months, when he went to the Hot Springs. He remained at the Springs for three months, was rubbed with an enormous amount of mercury, and badly salivated twice. He went home, and at the end of two months eruptions again appeared upon the body, with also larger mucous patches than before, his tongue at this time giving him some considerable trouble by reason of the general soreness of the organ. At this time an old eczema of the hands, which had troubled the patient off and on all his life, broke out, and in combination with the syphilis gave him a great deal of trouble. He again went to the Springs and remained there for eleven weeks, during which time he took mercury internally quite freely. He again went home, and was apparently well for three months, when mucous patches and eruptions broke out, sores appearing at this time upon the penis. About five years after the beginning of the syphilis the patient fell under the care of a physician who again rubbed him freely with mercury, the treatment being continued for about six months. He improved for a time and then quit treatment, as such patients so frequently do; but again got worse and went back to the same physician, and for at least eighteen months took mercury in considerable quantity. He was then advised to go to Mount Clemens, Mich.; he remained there about fifteen months, and while there became entirely well of his eczema, the syphilis, however, never leaving him entirely.

In 1884 the patient consulted me for the first time. He had then unequivocal cerebral syphilis, and tuberculo-squamous syphilides in considerable number were scattered about the forehead, forearms, and thighs, with a few scattered squamæ upon the trunk. Scars of former pustular syphilides were visible upon the forehead, forearms, and legs; the tibiæ and sternum were excessively tender, and considerable pain was experienced at night. Cephalalgia was a constant symptom and gave the patient intense suffering. An apparently gummy ulceration, with several fissures, existed upon the penis, just back of the corona.

The tongue was rough, and coated with a thick, dirty, yellowish-gray fur, with marked dryness in the centre and posterior part of the organ. Several tubercular nodules were also observable, one in the centre of the tongue, and the others near its base, those upon the right side being especially marked. On inquiry I found that the tobacco and alcohol habits had been persisted in for a greater portion of the time that he had been under treatment, and, much to my surprise, he informed me that his physicians had not restricted him in the matter of either indulgence. The treatment at this time was very vigorous; cod-liver oil and iron were ordered, on account of the patient's marked debility. The mixed treatment and the iodide of potassium in saturated solution were given, the iodide being run rapidly up to a dose of three hundred grains per diem, and maintained at that point for three weeks, the

disease being completely resistant to treatment until the end of that time. Local applications of the acid nitrate of mercury were made to the tongue from time to time, and with apparent benefit. As soon as the symptoms began to yield to treatment the dose of the iodide of potassium was diminished to about sixty grains per day, the tonics being meanwhile continued. At the end of three months the patient was free from trouble, with the exception that his tongue was more thickly coated than ever (psoriatic), and the nodules upon its surface were still perceptible. No amount of care and treatment ever caused this condition of the tongue to disappear entirely, and, as the history will show, it subsequently became the source of terrible trouble. The case remained comparatively well until about five months ago, the tongue creating some uneasiness from time to time on account of commencing ulceration of the nodules upon its surface, but yielding rapidly to treatment. On each occasion, however, the nodules and furring of the tongue became more prominent, and remained so in spite of treatment, the furring becoming a sort of membranaceous deposit, like wet chamois leather, which reformed as fast as it was removed.

At this time, while at the Hot Springs under the care of Dr. Vaughn, the tongue began to swell, and assumed a threatening appearance; the nodules began to ulcerate, and at one time a severe hemorrhage occurred.

I have not received the complete history from Dr. Vaughn, but suffice it to say, that after all means of treatment had been tried for two months without avail, the case was pronounced probably cancerous by the attending physician and several others who saw it in consultation. At this time Dr. Vaughn referred him to me with a view to possible excision. Upon examination I found the tongue filling the mouth and pressing upon the teeth in such a manner that it had become eroded and ulcerated by them. Salivation was profuse; a deep ulcer existed at the centre and back part of the organ; the enlargement seemed to be rather more marked upon the right side. The submaxillary glands were slightly enlarged; there were no other lesions present upon any part of the body.

Microscopical examination at this time failed to demonstrate the presence of cancer. No further examination of the tissues was made until after the tongue had been excised.

As the patient experienced great difficulty in masticating and swallowing, he was subsisting entirely upon fluid food, and, not being very robust primarily, had become greatly emaciated. The treatment instituted was chiefly a tonic one, in conjunction with an alterative mixture containing iodide of sodium and the chloride of gold; milk punches were allowed, and the patient instructed to take as much sweet cream and milk as he could without creating digestive disturbance. Local applications were made of a compound of carbolic acid, iodine, and menthol, in mild strength. Improvement was at first very rapid, and at the end of a week the tongue was nearly reduced to its normal size. In a few days, however, it again enlarged upon the right side, this enlargement being peculiar in that it was limited by the raphe, the tongue being at least double the thickness upon the right side that it was upon the left. The appearance was precisely the same as that presented by several cases of acute glossitis that I have seen, and resembled it strongly in the rapidity of its appearance; the increased thickening having come on within twenty-four hours. This condition of the right side of the tongue soon subsided, but was succeeded by enlargement of the tubercular nodules previously mentioned, and by the appearance of several new nodules. These appeared not upon the margin of the tongue, but upon its upper surface. In a few days the left side of the tongue underwent a diffuse enlargement, precisely similar to that which had occurred upon the right, and in exactly the same way subsided, and was succeeded by the development of tubercular nodules. The whole tongue now gradually increased in volume, and became so large that it hung over the edges of the teeth and protruded through spaces left by the extracted teeth. There was little or no pain, and such as there was was referred by the patient to the "holes," as he expressed it, worn in the tongue by the teeth. As soon as the case began to get worse the chloride of gold, or alterative mixture, was stopped, and the iodide of potassium was again run up to three hundred grains per diem; there seemed to be some improvement, and the drug was stopped for two weeks. At the end of this time it was again begun, as the case had again assumed a threatening aspect, and was now increased to the enormous dose of six hundred grains per diem. I soon became convinced that the iodide had lost its effect, and was producing no result, unless perhaps increasing the swelling of the tongue. Mild inunctions of mercury were tried next, at the suggestion of a professional friend, but they merely served to make the case worse, as had been my experience with his previous troubles.

Punctate cauterization with the galvano-cautery was tried, with some reduction in the size of the tongue. Soon after this, however, sloughing began, and destroyed the greater portion of the right side of the organ, the remainder of the tongue being undermined and eroded, and the floor of the mouth extensively invaded by the central ulcer, of which mention has already been made. During this time I exhibited the patient to a number of my professional friends, among whom were Drs. Hawley, Hayes, Zeissler, and Baxter, all of whom pronounced the trouble syphilitic, agreeing with my own diagnosis.

The case went on from bad to worse, many different plans of treatment being tried without avail. The sloughing continued until the tongue was in such a condition that even if healing had been possible the organ would have been practically useless. The base of the tongue was a foul mass of hyperplastic ulcerating tissue, the odor and secretion from which were not only offensive to the patient but were prominent factors in producing the constitutional disturbance. There seemed to be no hope of benefit from either internal or local medication, and, in addition, the malignancy of the process appeared to be now established As the patient was anxious to have something done to remove the foul and stinking mass from his mouth, I proposed excision with the galvano-cautery, an operation to which he readily consented.

*Operation.*—The operation was performed on July 30, 1888, with the assistance of Drs. P. S. Hayes and W. S. Walker, and Mr. Knight, medical student. The Fleming battery was used, with a platinum wire of moderate size. A preliminary tracheotomy was not performed because of the objections of the patient. Great difficulty was experienced in the operation, on account of the necessity of separating the tongue longitudinally, there being a large mass of ulcerating hyperplastic tissue at the base of the organ which required removal. It was found to be impossible to transfix the base of the tongue transversely with a needle, and at the same time it was necessary to have something as a purchase for the wire. A stout needle with a long double thread, to prevent its being detached and swallowed, was passed obliquely from above downward and forward as far back upon the base of the tongue as was practicable, a long needle-holder being used for this purpose. The wire was slipped over the needle and made to include as much of the base of the tongue as possible. The anterior portion of the tongue was readily included in the loop, as it was separated from the floor of the mouth in such a way that the electrode needle was readily pushed beneath it. A small amount of chloroform was first given, as I had found by previous experience that the patient was extremely resistant to ether. As soon as he was under full anæsthesia, however, ether was substituted for the chloroform and acted satisfactorily. The current was turned on and the operation begun, when, to my embarrassment, the patient became so asphyxiated that respiration ceased and the pulse at the wrist was hardly perceptible. I immediately detached the wire from the tongue and inverted the patient, my assistants at the same time performing artificial respiration. In about

five minutes the patient breathed as naturally as ever, and I was enabled to proceed. The current was again turned on, and the tongue about half burned through when the patient again became asphyxiated, apparently by the smoke produced by the burning of the tissues in combination with the accumulation of blood and mucus in the pharynx, there being quite free bleeding from a couple of teeth that were loosened in their sockets in the attempt to pry the jaws open while performing artificial respiration. The inverted position and artificial respiration were again resorted to, but it was fully fifteen minutes before it was considered safe to proceed. The tongue was finally completely excised. About the time the operation was completed the patient again stopped breathing, and a repetition of the previous performance of resuscitation became necessary.

I would not advise an operation of this kind to be performed without a preliminary tracheotomy; I certainly should not want to perform it again myself unless the patient would consent to be tracheotomized. The operation altogether occupied about two hours. The patient, three hours after the operation, was able to get aboard a street-car and ride to the hospital. At the end of a week the eschar produced by the cauterization became detached and left a surface of fairly healthy appearance; the fetor of the breath was improved and the sloughing of the base of the tongue ceased. The floor of the mouth healed nicely, and remained in a tolerably healthy condition for several weeks; the submaxillary glands became smaller, and the general condition of the patient improved considerably. About a month after the operation, however, the submaxillary glands again enlarged, becoming larger than ever, and quite tender. There was comparatively little pain save a moderate amount of cephalalgia and otalgia. The ulcerative process on the floor of the mouth recurred, but did not progress rapidly nor ulcerate extensively. A small ulceration formed upon the right pillar of the fauces. These symptoms practically settled the question of malignancy. Professor I. N. Danforth, having examined the specimens excised, informed me at this time that the case was of a sarcomatous character, but I inferred from his report that it did not present typical characters. About two months after the operation an abscess formed in the submaxillary glands; this, when opened, gave exit to a thin, sanious fluid. Pain at this time was very severe. At the end of about three months an occasional slight hemorrhage from the mouth occurred. The patient finally died, about four months after the operation, from a sudden hemorrhage occurring during the night.

This unfortunate case is, in many respects, unlike any other that I can find on record. The literature of the subject is very meagre. During the course of the disease there were present distinctive features of several forms of glossal affection. During the four years that the patient was under my observation the tongue presented gummy nodules and ulceration, lingual psoriasis, diffuse syphilomatous deposit, and latterly attacks of subacute glossitis. At various times before coming under my observation—and once since, as shown by the history—mercurial stomatitis occurred, and formed an important feature of the case, particularly, I think, as regards the etiology of the process which finally necessitated removal of the tongue. Prior to extensive destruction of the organ these various conditions merged into a general hypertrophy, the tongue becoming extremely indurated. These various features must be taken into consideration in studying the case.

Macroglossa, or hypertrophy of the tongue, of a simple character is very rarely seen, and few cases are on record of congenital origin. According to the published researches of Fairlie Clark,[1] hypertrophy of the tongue occurring later in life may arise "spontaneously" (?), or from wounds, mercurial salivation, or as a consequence of diffuse inflammation from scarlet and other forms of fever. I will also add to these causes constitutional syphilis.

Attrition against the teeth in these cases of macroglossa produces from time to time attacks of acute or subacute glossitis, each of which leaves the tongue more enlarged than before (König).[2] This has been a prominent feature of the case at present under consideration. The best authorities have recommended for the cases of simple macroglossa the use of astringent solutions in combination with compression. It is obvious that the latter measure is not applicable to cases like my own, whether malignant or not, in which necrosis of tissue is such a prominent feature. Clark reports forty-three cases, nine of which were cured by compression and astringents. In some cases excision of portions of the tongue has been performed with a successful result. This measure was not to be thought of in the case under consideration.

The causes which operated in the production of the lamentable condition of my case were, in my estimation, several. In the first place, it will be conceded that the numerous attacks of glossitis and stomatitis necessarily left the tongue in a more or less damaged condition, and caused a chronic condition of irritability which favored a deposition of syphilomatous material in the organ at any time when the constitutional disease should become active. That the prolonged and injudicious use of mercury, independently of salivation, is prone to induce inflammatory and ulcerative processes of the mouth and the structures contained in its cavity I firmly believe. Authors are united in the view that the excessive use of mercury is a frequent cause of glossitis. It is probable that the excessive, although necessary, use of iodide of potassium still further enhanced the morbid condition of the tongue. It is reasonable to suppose that such might be the case when we take into consideration the fact that the salivary glands are heavily taxed in the elimination of iodide of potassium as well as of mercury.

The continued use of alcohol and tobacco, in combination with the irritation produced by diseased teeth, completed a chain of circumstances which, in combination with the syphilitic cachexia, favored the development of the morbid process in the tongue.

The condition known as ichthyosis or psoriasis of the tongue is due to the same causes as generalized glossitis, and is really part and parcel of that process in which the inflammation is localized upon the surface of the mucous membrane.

According to Hulke,[3] ichthyosis of the tongue consists essentially in hypertrophy of the epithelial and papillary elements of the mucous membrane. The relation of ichthyosis or psoriasis of the tongue to syphilis and cancer is very important, and all authorities unite in acknowledging its relation to syphilis, although it may occur in non-syphilitics. In appearance it resembles, in some cases, a deposition of wet chamois leather upon the surface of the tongue, as described in my case, which rapidly reforms after removal. In other instances it resembles a thin layer or film of coagulated albumin, and in these cases each successive deposit is more dense and adherent than the preceding. The condition is prone to develop epithelioma, as Weir[4] has shown most conclusively by the history of 68 cases, of which number 35 eventually developed epithelioma.

Hutchinson has also advanced the opinion that cases of syphilitic disease of the tongue are especially prone to develop epithelioma later in life.

That a condition similar to that of my case may undergo a transition into epithelioma or malignant sarcoma seems plausible, and such a transition I believe to have occurred in this instance. The presence of epithelioma, or its subsequent development in such a case, would be no argument in my estimation against the accuracy of the previous diagnosis of syphiloma, inasmuch as it is conceded by the best authorities that such processes are prone to undergo a malignant transition. The course of this case and its history are widely different from the ordinary

[1] Diseases of the Tongue.

[2] Lehrbuch der specielen Chirurgie, 1878.

[3] Clinical Society Reports, vol. ii., p. 1.

[4] New York Medical Journal, March 18, 1875.

clinical features of epithelioma of the tongue. Epithelioma of the tongue, beginning four years ago, would not have lasted as long as this condition. The average duration in cancer is less than two years. The age of the patient would warrant a doubt as to the existence of carcinoma, cases under forty years of age being very rare.

There was at no time in the history of the case a cancerous cachexia, and the constitutional condition fluctuated quite markedly, depending upon the amount of nourishment that the patient was able to take. Several weeks after the operation he was in better flesh than at any time for two months previous.

The attacks of glossitis which occurred from time to time necessarily modified the clinical aspects of the case, and obscured the distinctive points in differential diagnosis. There are some features, however, that deserve mentioning in contradistinction to those of ordinary cases of cancer. The enlargement of the tongue was general, and the sloughing began at several points, this being decidedly unlike cancer, which is usually localized at the beginning, invades successive areas of the tongue, and does not attack more than one point, from which it gradually progresses. The induration in cancer extends with the ulceration, while in this case it became general before the ulceration had advanced to any extent. The ulceration, instead of beginning underneath the tongue or at the border of the organ at some particular point, as is the case in cancer, first attacked the tubercular nodules previously described upon the upper surface of the tongue near its centre and base. One peculiar feature of the process was a clean dissection of one-half of the organ, the process being temporarily limited at the raphe; a line of progression that is very noticeable in syphilitic conditions, and which has given rise in my own mind to the belief that some of the late lesions of syphilis are of a trophic character and the result of the syphilitic impression upon the sympathetic nervous system—a point upon which I will expatiate more fully in a subsequent paper.

There was a marked improvement from time to time in this case. Indeed, there were times when it seemed as though the disease was under control and recovery probable. In this respect there was a marked contrast with the classical course of cancer, in which the disease grows progressively worse until its close. After the operation the parts assumed a healthy appearance, the tendency to bleeding was entirely checked temporarily, the disagreeable odor disappeared, and the patient assumed a better color than before.

In ordinary cancer the tongue becomes absolutely immovable, while in this case there was some mobility at all times, and considerable during the periods of temporary improvement. The tongue was left harder and more indurated after each exacerbation of glossitis. The absence of pain until late in the case was quite remarkable, and presented a marked contrast to the course of cancer, in which the pain is usually very severe. The persistent enlargement of the lymphatic glands at the angle of the jaw was the most suspicious symptom in the case, as indicative of possible or probable malignancy, yet I think too much stress has been laid upon this feature of glossal troubles as pathognomonic of cancer; for, although late syphilitic lesions do not produce enlargement of the glands *per se*, the septic process which results from necrosis of the tissues, and the decomposition of food which may adhere to the uneven surfaces of ulcerations upon the mucous membrane, may give rise to irritation of the neighboring glands. Thus it seems that it is by no means necessary that cancer should exist in order that lymphatic glandular reaction may be produced.

In view of the great danger of processes similar to those which so long existed in my case, resulting in the development of malignant disease, it would seem that we would be justified in adopting some radical measure. Had I to go through with a similar case again, I should profit by my experience and destroy the tubercular nodules as well as the thickened mucous membrane upon the surface of the tongue with the actual cautery. There is, of course, no means of proving the success of this line of treatment, and I may never have an opportunity to put it into practice on account of the rarity of such cases; but I believe that had it been done in this instance the malignant process might never have developed. No remedy short of actual destruction would seem likely to be beneficial to such conditions. The only remedy which ever seemed to effect the ichthyosis of the tongue in this case was a saturated solution of salicylic acid, which seemed to check the progress of the disease and improve the condition of the tongue for some little time, when it finally lost its power.

The precise period at which a malignant was substituted for a syphilitic process would be hard to determine. I am by no means convinced that the diagnosis of syphilis, made several months before the operation of excision of the tongue, was incorrect. The course of the case was certainly unique. Whether the time of the transition into a malignant process could have been determined by frequent microscopical examinations is questionable. Such microscopical examinations of the case as were made were at the hands of competent microscopists; but I am free to say that the results were hardly satisfactory, nor do I think that they themselves considered them to be be so.

The condition present in the case which I have related might have been mistaken for tuberculosis of the tongue. The history and course of the case, however, militated against such a diagnosis. Tuberculosis is rare as a secondary condition, and still rarer as a primary disease of the tongue. In twenty-six cases collected by Delavan,[1] nine out of twenty-six were primary; in this series the primary cases were of greater than the average frequency.

Such cases certainly serve to impress upon us the necessity of recognizing and radically treating precancerous states of the tongue. Mr. Butlin, in a recent essay before the Harveian Society of London,[2] stated that in quite a number of cases which had been under his observation carcinoma of the tongue had been preceded by a condition which was so definitely associated with the subsequent development of cancer as to deserve the designation "precancerous." This condition he observed in over seventy per cent. of cases of lingual carcinoma. Papillomatous or warty growths were apparently the most dangerous of the morbid states which actually and immediately preceded the development of cancer. Such warty growths he showed to be much more frequent than was generally believed. The question arose as to whether it would be proper in cases of leucoma (leucoplakia buccalis?) and chronic glossitis of a superficial character, in which warts or warty growths develop on the surface of the tongue, to remove the entire diseased area, or, at least, the anterior portion of the organ, instead of, as is usually done, removing the warty growth with a certain area of the surrounding tissue. Two cases were related in which wart-like growths developed on tongues affected by leucoma, and were removed, and in which, later on, carcinoma developed, but not at the site from which the warts had been removed. The internal administration of liquor arsenicalis was advised in all cases of chronic disease of the tongue which were associated with various forms of chronic disease of the general integument of a non-specific character. Several cases were also related to demonstrate the advantage of early excision of cancerous affections of the tongue. In view of the fact that in chronic syphliitic, or other affections of the tongue, protracted irritation is apt to develop cancer in the already degraded tissues, it is desirable to avoid applications of an irritant character. The nitrate of silver particularly ought to be used cautiously as a stimulant or astringent, but never as a caustic. When it seems desirable to destroy portions of diseased tissue by means of caustics, the galvano-cautery is the best method for accomplishing the object. In lieu of this, some active cauterant should be employed, such as chromic or nitric acid.

## Clinical Department.

### THE SEQUEL OF THE CASE OF CEREBRAL ABSCESS TREATED BY TREPHINING.

DR. J. W. WRIGHT, of Bridgeport, Conn., writes: "The sequel of the operation for cerebral abscess detailed in THE MEDICAL RECORD of September 21, 1889, page 317, should now follow, since it reveals the cause of both the abscess and the failure of a permanent cure. In September the patient again commenced to fail, from a recurrence of his former symptoms, and a second operation was performed by the surgeon then on duty, Dr. Worden, September 21st. A small quantity of pus was found and a drainage-tube inserted, but patient died on second day.

"The autopsy revealed the fact that a wire nail two inches long had been driven through the skull into the brain, the head of which was sunk into the bone. It had entered the left parietal bone close to the sagittal suture, two inches in front of the occipito-parietal sutures. The point was the centre of an abscess in the white substance of the brain, which involved the parietal lobules and encroached upon the post-central convolutions. The abscess had not ruptured into the ventricles.

"From facts since disclosed, it is probable that the nail was driven into his head on May 17th, by falling on some boards containing nails of that size and style."

### TWINS WITH ONE PLACENTA.

DR. J. H. STRAUGHN, of Lexington, Mo., writes: "January 31, 1886, I was called to see Mrs. J. W——, in labor. After the birth of the first child, on making an examination, I was satisfied that there was another child in the womb. After tying the cord of the first child, I made traction on the cord for the purpose of delivering the placenta, but the woman complaining that 'I was killing her,' I desisted. In a short time labor pains set in again, and the second child was soon born. I then delivered the placenta, and found that there was but one for the two children. The umbilical cord of each child was attached near the periphery, about equidistant in each case. The children were both girls, one weighing four, and the other four and a half pounds. They are both alive and well at this writing, so far as I know."

### LATE PREGNANCY.

DR. J. S. DOLSON, of Hornellsville, N. Y., writes: "In accordance with your request for reports of late pregnancies, I send you the report of one in my practice, many years since. Mrs. S——, County of Steuben, this State, was confined in the summer of 1856, she being then fifty-two years of age. This was her fifth confinement and the sixth child, having had one pair of twins. The same week that I attended the mother, fifty-two years of age, I also attended the daughter, aged twenty-two."

CHARCOT'S OPINION OF PROFESSIONAL WOMEN.—M. Charcot, one of the jury of the Faculty of Medicine in Paris, in complimenting a young lady who had obtained her doctor's degree, said that "women pass their examinations, when they do pass them, even more satisfactorily than men; but what will be always a bar to their success is that they have no real love of their proposed profession. What they aspire to is the first rank, the most prominent posts, the most lucrative offices; and what they dislike is the humble and unpleasant, but necessary, service of humanity, such as is given by the hospital dresser." Curious, but precisely the same thing might just as correctly be said of men.—*Chemist and Druggist.*

## Progress of Medical Science.

OPERATIVE TREATMENT FOR PROSTATIC HYPERTROPHY.—Professor Kümmel, of Hamburg, in a paper lately read before the Congress of the German Society of Surgery, stated that he had performed on six patients a partial extirpation of the hypertrophied prostate gland. His cases were very grave, as they had resisted all other methods of treatment. There was fever, bronchitis, and considerable vesicular dilatation. In such cases the operation is indicated, while it is the contrary when the kidneys are seriously involved, or when there is a complete paralysis of the bladder. In this last case the operation is useless, for even after the suppression of the obstacle spontaneous micturition cannot be re-established. To extirpate the prostate gland he performs superior cystotomy; the bladder is very carefully washed out, and he then destroys, by the aid of the thermo-cautery, not only the median lobe, but also all the parts of the gland which project into the bladder. He then sutures the bladder, and allows Nélaton's sound to remain in it. Out of six patients, one died from collapse, in another the operative result was negative, four are cured and can urinate spontaneously. In the discussion that followed, Professor Socin, of Bâle, said he believed the enlarged prostrate was not so often accountable for the evil symptoms observed as is the cystitis, which is so frequent a concomitant. He thought that the good results which sometimes follow extirpation of the prostate gland are due, probably, more to the washing out of the bladder and to the sound left in position—that is, to the treatment of the cystitis—than to the operation itself. The cystitis is the first enemy to combat in the treatment of prostatic enlargement.—*Medical News.*

INSANITY FOLLOWING MUMPS.—Dr. R. Percy Smith, Medical Superintendent of Bethlem Hospital, London, England, has recently called attention to the occurrence of insanity as a sequela of mumps, giving two illustrative cases which came under his own notice (*The London Medical Recorder*). A lad, aged nineteen, had had good health previously, and there was no neurotic family history. A fortnight before admission he had suffered from mumps, which was epidemic at the time in the district. The attack was complicated with exhausting diarrhœa. Five days before admission he became excited and passed into a condition of acute mania, from which he rapidly recovered in Bethlem. The other case was that of a young medical man, who, after an attack of mumps complicated with severe orchitis, became depressed, suspicious, and suicidally inclined. He recovered after a time, without its having been necessary to send him to an asylum. Dr. Smith thinks that in each of these cases the extreme exhaustion caused by the complication of diseases had more to do with the induction of insanity than fever or metastasis.

EFFECTS OF PROLONGED CHLOROFORM ANÆSTHESIA.—Some observations, made about two years ago by Dr. Ungar, pointed to fatty degeneration of the heart and liver as the cause of death after repeated prolonged administration of chloroform. Further experiments on dogs have recently been made by Dr. Strassman, which appear to confirm this view. Dr. Strassman found that the first organ to be affected was the liver, then the heart, and after that other viscera. The nature of the morbid change was not a fatty degeneration, but fatty infiltration. The actual cause of death in fatal cases appeared to be the cardiac affection, as in all such a very marked degree of change was found in the heart. In non-fatal cases the morbid change was found to have disappeared in a few weeks' time. When morphine was given previous to the chloroform, less of the latter was required, and, consequently, the changes produced were not so considerable as when the ordinary amount was given. Animals suffering from hunger, loss of blood, etc., were especially predisposed to the morbid changes due to chloroform.—*The Lancet.*

## THE BRAIN-WEIGHT OF MAN AND WOMAN.

THE subject of the comparative weight of the brain of man and woman comes up periodically, and almost always some incorrectness of statement or inadequacy of knowledge is to be observed. Perhaps a certain feeling of gallantry tempts speakers and writers to handle tenderly facts apparently in conflict with the view that woman is encephalo-morphologically the equal of man.

The average weight of the male brain is 49½ ounces—of the female, 44 ounces; a difference of over five ounces. Woman's brain has a higher specific gravity. The man has a larger brain in proportion to stature (Marshall), but woman's brain is larger in proportion to her weight. In 239 Russian brains (Buchstab) the ratio of body-weight to brain-weight was for the male as 38 to 1; for the female, 35 to 1. In woman the brain is shorter in the sagittal diameter, being from 6⅞ to 6¾ inches in man, 6 to 6⅜ inches in woman (Huschka). The transverse and vertical diameters are more nearly equal in the two sexes.

The frontal lobe is better developed in man, the distance from the anterior extremity of this lobe to the upper end of the fissure of Rolando being in males 152.9 mm.; in females, 140.6 mm. (Buchstab). On the other hand, the occipital lobe is more developed proportionately in woman, the distance from the point of the occipital lobe to the parieto-occipital fissure being in males 48.7 mm.; in females, 51.4 mm. This is for Russian brains, which are a little smaller than German and English, a little heavier than Italian and French brains.

The difference between the weight of brain in man and woman increases with civilization, and is most marked in the Caucasian races. In Parisians this difference amounts to 222 grammes, or nearly seven ounces; in European nations generally, 163 grammes; in Hindoos, 120 grammes; in Australians, 103; in negroes, 82; in Chinese, 15.

The greatest sexual difference as regards brain-weight is found at birth, when the female brain weighs 347 grammes, and the male 393, or about ⅛ more, while the total weight of the male infant is about $\frac{1}{15}$ more than that of the female. The female brain begins to lose weight after the age of thirty, that of man not till ten or fifteen years later. The loss in woman is very slight, however, and she keeps up a high brain-weight much later (till seventy) than man, so that in old age the difference in brain-weight is reduced to its minimum, or a little over three ounces.

Definite statements cannot be made regarding the sexual differences in convolutional complexity, or the thickness of the gray matter, two very important points in estimating the intellectual powers of the organ.

Despite much loose talk regarding the unimportance of brain-weight as a test of intellectual superiority, it is unquestionably an important factor. What Thurnam calls medium brains range in weight between 40 and 52½ ounces for men, and 35 and 47½ ounces for women. All brains in size above this are called megalocephalous. Now the tables of brain-weights collected by Bastian and others show that the proportion of great men who are decidedly megalocephalous is twenty-five per cent., while the proportion in average men is four per cent. to five per cent. The proportion of incipient megalocephaly (*i.e.*, weight above 52½ ounces) among eminent men is nearly sixty per cent. There can be no doubt that the majority of eminent men have large brains, just as the majority of ordinary men have forty-nine-ounce brains. Certain individual cases furnish exceptions, and distinguished talent can coexist with a small brain, but it is not the rule.

When a brain falls to a weight of 37½ ounces in a man, or 32½ ounces in a woman, it is called microcephalic, and the rule is that below these limits idiocy exists. There is just five ounces less amount of brain-matter, however, needed to keep a woman from idiocy than is needed for a man. Hence we may reasonably suppose that this, which is nearly the average difference in brain-weight of the sexes, represents not tissue necessary for mentality, but corresponds with the smaller muscular mass and shorter stature of woman.

## THE INVASION OF THE "MASSEUR."

WE must beg our readers to keep a close eye upon the *masseur*. He is bearing down upon unhinged humanity with a steady and relentless stride. He develops in the midst of us, he sails over from Germany and England to us, while, if there are any graduates of Heilgymnastik still left in Denmark, Sweden, or Norway, we should like to know it; for it has appeared to us, after some busy morning, that they have all called. Truly, the *masseur* is among us. He is a man of great resources. As his fraternity increases, he does not lose heart, or complain of competition, or seek protection from the State—he simply enlarges his field. In olden times the rubbing of a stiff knee with officinal linimentum saponis was the centre and circumference of massage; soon, however, we learned how soothing was the emollient and theobromated hand upon the hyperæsthetic skin and diseased muscle. The *masseur* became firmly established as the resourceful prop of hysteria and unfailing staff of morbid locomotion. But then the sinewy and insidious hand began to gather adventitious aids, and seek new worlds to conquer. Having organized its movements into a company of Gallic polysyllables, so that its manœuvres of *tapotiment* and *pétrissage* and *effleurage* should not be mistaken for plain, every-day slap-slap, jab-jab, and thump-thump, it proceeded to attack all the several diseases and organs of the body. Adipose tissue in excess was made to disappear, while glandular tissue, if mammary, was rubbed to make it grow. Massage has now applied itself to diseases of the eye, and granular lids are, *quoad* the granulations, artistically rubbed off; it has invaded the mouth and throat, reducing hypertrophied tonsils,

opening the Eustachian tubes, and curing catarrh and deafness. The abdominal viscera were the early and easy subjects for this now illustrious science. The colon's lax vermicular waves are tempestuously hastened, and the modest stream from the smaller bowel has scarcely babbled through the ileo-cæcal valve before it is rushed madly into the rectum. The pelvic organs have of late received the devoirs of this new art; and the uterus has been rubbed and stroked and pommelled, all in pure French terminology, until this martyr-viscus could not help but free itself from adhesions and congestions, and pillow itself gently on its original vesical cushion. Lastly, we learn that the heart is to have massage. The heart has been, we are told by poets, torn and bruised, and bled and broken; but it remains for modern science to see that it shall have *effleurage* and lomi-lomi.

There are still a few things left for the *masseur*. Can he not apply *tapotiment* to the brain, or, at least, to the cerebellum? Has he done justice to the kidneys? Might not the ovary receive a course of artistic jabbing before it is removed and bottled. When all fields are conquered, and every viscus springs responsive into blooming juvenescence beneath his learned touch, we recommend the *masseur* to Christian science.

### FIFTY YEARS OF COUNTRY PRACTICE.

Dr. Alonzo Garcelon, ex-Governor of Maine, is seventy-six years old and is still in the active practice of his profession. He this year completes the semicentennial of his medical career. The Lewiston *Journal* gives us some gossip regarding the doctor's life-work, but particularly about his travels. He estimates that with his horse and chaise he has driven about three hundred and sixty thousand miles, or fourteen times around the earth. Such an estimate is based on the supposition that he has travelled an average of a little less than twenty miles a day, or seven thousand two hundred miles a year.

This is, perhaps, a rather high estimate, but it is quite within the bounds of possibility.

The reflection which occurs to one in contemplating these figures is that an enormous amount of purely mechanical and unproductive labor has to be expended by the country doctor in his daily work. While this time is not by any means all lost, for there is health and mental rest, or, perhaps, productive ratiocination, in a moderate amount of ambulation, yet three hundred thousand miles is too far for the average man to go with horse and carriage, and expect to do the highest class of work in life.

It is all the more credit to Dr. Garcelon that he has succeeded in travelling pretty nearly as far as to the moon and back, and yet has acquired both political distinction and medical prominence. But the country practitioner most needs a means of locomotion swifter than the horse. Dr. Garcelon in riding his three hundred and sixty thousand miles has had to give up nearly seven solid years, and twenty years of working days out of his total fifty, simply in riding to his patients and home again.

### AN "INFALLIBLE ANTIDOTE" FOR MALARIOUS FEVERS.

Dr. Charles G. R. Naylor, Civil Surgeon, of Burmah, India, addresses a report to the Deputy Surgeon-General of British Burmah in which he asserts that carbonic-acid gas is an infallible antidote to malarious fevers of all types and durations. Dr. Naylor's report is republished in Edinburgh. It was first made eight years ago, but is now put forth again in an enlarged form and with the emphasis and confidence drawn from a fuller experience.

Dr. Naylor does not claim originality for his treatment. It was devised or discovered by Dr. John Parkin, of London, who tested its value while visiting the malarious districts of Italy, Spain, and West Africa.

The *rationale* of the gas treatment is expounded by Drs. Parkin and Naylor, but it is far from being satisfactory or scientific and it need not occupy our space.

The gas is administered in solution and is got in its cheapest form by dissolving bicarbonate of soda, gr. xxx., in three ounces of cold water, and throwing into the solution tartaric acid, gr. xx., in a powdered state, the mixture to be stirred rapidly once, and swallowed as soon as possible in a state of effervescence. The patient must be made to lie down immediately after, to prevent eructation and escape of the gas, so apt to occur in a sitting posture.

The doses of soda and acid must be decreased to suit the different ages of children, as gr. xxx. of bicarbonate of soda are not soluble in the small quantity of water suitable for administration in one dose to very young children.

Sometimes the soda is given first and followed by the acid.

The remedy is best administered just before the paroxysm is expected, or in the remission if the case be one of remittent fever. Dr. Naylor cites a long list of cases cured by the gas.

## News of the Week.

Dr. Carl Koeler, the discoverer of cocaine anæsthesia, has been made Instructor in Ophthalmology at the New York Polyclinic.

The Chicago Medical Library Association, incorporated in September last for the purpose of securing and maintaining a library for the advancement of the medical and kindred sciences, held its first regular meeting on October 4th, at the Grand Pacific, at which the following were elected officers: *President*, Dr. N. S. Davis; *Vice-President*, Dr. Edward A. Lee; *Secretary*, Dr. Bayard Holmes; *Treasurer*, Dr. E. Ingals. Dr. William F. Smith was made a Director in place of Dr. Mary H. Thompson. —*Journal of American Medical Association.*

The Southern Surgical and Gynecological Association will hold its next meeting in Nashville, Tenn., November 12, 13, and 14, 1889.

New York Obstetrical Society.—At the annual meeting of the Society, held October 15th, the following officers were elected for 1889–90: President, Dr. J. E. Janvrin; 1st Vice-President, Dr. H. C. Coe; 2d Vice-President, Dr. R. A. Murray; Recording Secretary, Dr. A. M. Jacobus.

The Beaumont Medical College, of St. Louis, was burned to the ground recently. The Faculty have, however, secured another building, and the lecture course will be continued.

"GYNAIA," A NEW DISEASE.—A Dr. Steinerkopf, who may be some relation to Dr. Holzerkopf, or perhaps Dr. Dammkopf, has discovered a new disease which he calls "gynaia," and which he defines as "the simulated existence of feminine moral qualities in the person of a man." An acute and learned commentator of Dr. Steinerkopf's disease thus describes it editorially in the *New York Medical Journal:* "The discovery made by Dr. Steinerkopf is, that what has been yclept effeminacy is in reality a disease which is curable, and not a concomitant of congenital anorchidia, or a resultant of an early training analogous to the subalar rearing of the offspring of a uniparous hen, when occurring in a male. This disease, "gynaia," is characterized by the exhibition of timidity, aversion to tobacco and to dogs of non-personal allegiance, manners of ratiocination untrammelled by the friction exerted by logic, and other qualities commonly observed in the typical human female."

GASTROTOMY FOR A SET OF FALSE TEETH.—It is stated by Connecticut papers that a young woman of Bridgeport, a domestic, who swallowed, or thought she swallowed, a plate of false teeth, was subjected to the operation of gastrotomy without finding the teeth. She still complained of agonizing pain and was sent to a hospital in New York, where (the doctors having been put in possession of all the facts) a second gastrotomy was performed, and on her recovery from ether a set of teeth prepared for the occasion was shown her, and she at once recovered from all pain and discomfort.

A CASE OF HYDROPHOBIA is reported to have occurred at Astoria, L. I. The disease attacked a saloon-keeper who had been bitten by a dog three months before.

DR. IRA HAWLEY BARTHOLOMEW, aged sixty-one, ex-member of the Michigan House of Representatives, ex-President of the State Medical Society, ex-President of the Michigan Agricultural Society, and who held the office of Mayor of Lansing, Mich., for three consecutive terms, died October 18th, of bronchitis. Dr. Bartholomew was well known in the medical world, and was a contributor to the prominent medical journals of the country.

MEDICAL SCHOOL DISTURBANCES IN CANADA.—A telegram from Montreal states that the students of Victoria Medical School are still in opposition to amalgamation with Laval. The Church has taken the matter in hand. Archbishop Fabre has sent the following letter to the Rev. Mothers Superior of the Hotel Dieu and the Catholic Maternity Hospitals: "On account of particular circumstances, I have ruled that no student in medicine can be admitted in your wards to follow a clinical course, unless he is bearer of a card of admission reading as follows: 'Laval University, Montreal; School of Medicine and Surgery of Montreal,' and signed by Drs. Mignault and Foucher, Joint Secretaries." It is believed that the students will now yield to the action of the authorities in uniting the Laval and Victoria Medical Schools.

MEDICAL CO-EDUCATION.—The announcement is made that the University of Pennsylvania contemplates throwing open her classes for the admission of women. No exceptions are mentioned, and the wording of the resolution, which was passed by the Faculty with but two dissenting votes, warrants the inference that the school of medicine was included.—*Times and Register.*

ROYAL LEPERS.—After having made out Francis I. and Henry VIII. syphilitics, the Russian emperors epileptic, the English scrofulous, the Bavarian imbecile, and the Spanish the last in stages of degeneracy, historical critics are discovering leprosy among kings and princes. A writer in *Notes and Queries* says: "There is, I think, no doubt that Henry IV. of England and Robert Bruce were lepers. About Henry III. I am not sure. But I have tried to discover any authority for what I am quite sure that I read some years ago—but where I cannot remember—that Adelicia of Louvaine, second wife to Henry I., became a leper, and that that was the real reason why, when a happy wife and mother, she left her second husband, William de Albini, to whom she was tenderly attached, and entered a convent."

THE DISSEMINATION OF TUBERCULOSIS.—The Berlin correspondent of the *Medical Press* says: "I have already repeatedly alluded to the labors of Dr. Cornet, in the Hygienic Institute under the auspices of Professor Robert Koch, in regard to the dissemination and prevention of phthisis. Being a Bavarian by birth, he some time back sent a copy of his publications to the Bavarian Government, with the request that they should put the correctness or otherwise of his views to the test. It was not to be expected that they should undertake an extended inquiry at the dictate of a private individual, but they did pass on the writings to the Ober Medizinal Auschuss. The referent on the occasion, Professor Bollinger, has decided to enter on an investigation as regards prisons. It is notorious that a great number of prisoners, nearly one-third, die of phthisis. Professor Bollinger has determined that they shall not die of phthisis contracted within the prison walls, *i.e.*, if Koch's views on its etiology are correct. For the future, all cells are to be disinfected as thoroughly as after cholera or the plague. Further than this, all prisoners already phthisical, or suspected of being so, are to be removed. All sputa are to be disposed of in the way recommended by Dr. Cornet. The proposed experiment has all the appearances of being a crucial one, and the results will be watched all over the world with great interest."

TYPHOID FEVER AT YALE.—Several students at Yale are down with the typhoid fever, but nothing like an epidemic prevails or is feared.

A BILL TO ESTABLISH A STATE BOARD OF HEALTH has been introduced into the Legislature of Georgia, but has met great opposition, and from accounts given is not likely to pass.

WILKIE COLLINS A MORPHINE TAKER.—*The Medical Press and Circular* says: "It will be recollected that one of his most sensational novels was entitled 'Science and Heart,' and that it portrayed a demoniacal doctor who vivisects his own child in his craze for biological investigation. Those who were familiar with the author's earlier novels and the spirit of good-nature which pervaded them, wondered at the flights of crazy rhodomontade which this book contained, but it now appears that when it was written, and afterward, until his death, he was the victim of morphimania, and that the agony gush which he wrote was the outward and visible sign of the brain aberration produced by the continual and excessive use of the drug."

DR. EDWARD DEANS, at one time City Physician of Chicago, took a dose of morphine with suicidal intent on the 14th inst., and died on the 16th, at the County Hospital. He was seventy-one years old.

THE PRINCE OF WALES is reported to have Bright's disease. We trust he will not make that unpleasant affection the vogue.

A FEW SPORADIC CASES OF YELLOW FEVER have been recently reported at Key West, Fla.

A NEW MEDICAL COLLEGE has been organized at Wichita, Kan., with a corps of eighteen professors. Attendance on three full lecture-courses is required for graduation.

A DEATH FROM THE ADMINISTRATION OF CHLOROFORM is reported in the *Cincinnati Lancet-Clinic* by Dr. William L. Muzzey. The patient was an apparently healthy man, thirty years of age.

CONFERENCE OF INSANE ASYLUM SUPERINTENDENTS AND MANAGERS.—A conference of the superintendents and managers of asylums for the insane in the State of New York was held at Buffalo, October 9th. Dr. John D. Hill, President of the Board of Managers of the Buffalo Asylum, presided, and a permanent organization was effected. It was agreed to hold an annual convention, and that the next one should be at Binghamton, on the third Wednesday in September, 1890. Papers were read by Dr. J. B. Andrews, Superintendent of the Buffalo Asylum, Dr. P. M. Wise, of the Willard Asylum, and others.—*Boston Medical and Surgical Journal.*

A NEW HOSPITAL IN PHILADELPHIA.—Mr. John B. Stetson, of Philadelphia, who has organized much charitable work in that city, is building a hospital in connection with the North Fourth Street Union Mission. The hospital is nearly completed.—*Boston Medical and Surgical Journal.*

AS WE HAVE STATED BEFORE, in the judgment of those most competent and of those who have carefully examined Pasteur's antirabic inoculation methods, they are believed to be measurably successful in practice and to be scientifically legitimate. We regret to observe that our usually acute contemporary the *Medical Standara* has allowed itself editorially to commend the silly assertion of a rabid anti-Pasteurite that Pasteur "has never studied the subject of rabies or hydrophobia, and that he practises a clap-trap method without analogy in theory or practice in the whole round of medical experience, and which results in an absolute increase of deaths from hydrophobia!"

WHOOPING-COUGH.—Bromoform in doses of 5 to 20 drops daily, and phenacetin in 7 to 10 grain doses, are among the new remedies recently recommended for whooping-cough.

MENTHOL IN THE VOMITING OF PREGNANCY.—Dr. S. Gottschalk, of Berlin, reports a case of obstinate vomiting of pregnancy (*Berlin. klin. Woch.*, p. 875) which was promptly controlled by the internal use of menthol. The following formula was used:

℞. Menthol ..... 1
Alcohol. ..... 20
Water. ..... 150
M. Sig.: 3 j. q. 1 h.

# Obituary.

## PHILIPPE RICORD, M.D.,

PARIS, FRANCE.

THIS most famous of French physicians died at Paris, October 23d, in the eighty-ninth year of his age. It is probably not generally known that Ricord was an American by birth and education. He was born in Baltimore, October 10, 1800, and when a mere lad went to Philadelphia for the purpose of studying medicine. In 1820 he went to Paris, where, in March, 1826, he received the degree of M.D., and began to practise at Olivet, near Orléans. Two years later he returned to Paris, where he delivered a course of lectures on surgery, which gave him some renown, and in 1831 he was appointed Surgeon-in-Chief of the Hôpital des Vénériens du Midi. This post he filled most ably for nearly thirty years, retiring in 1860 on account of age. He had, in the meantime, acquired a great reputation as a specialist in venereal diseases. In 1862 he was appointed Physician in Ordinary to Prince Napoleon, and in 1869 became Consulting Surgeon to the Emperor Napoleon III., whom he had previously attended with great devotion during a severe illness. In return for his services the Emperor presented him with a snuff-box and twenty thousand francs. He became a Commander of the Legion of Honor in 1860, and a grand officer in 1871 for services as Chief of the Ambulance Corps during the siege of Paris. He was also the recipient of many foreign decorations. Ricord was not only a brilliant surgeon but a man of great learning and wit.

# Society Reports.

## AMERICAN PUBLIC HEALTH ASSOCIATION.

*Seventeenth Annual Meeting, held at Brooklyn, N. Y., October 22, 23, 24, and 25, 1889.*

FIRST DAY, TUESDAY, OCTOBER 22D—MORNING SESSION.

THE Association was called to order at 10 A.M. by the President, DR. HOSMER A. JOHNSON, of Chicago.

DR. J. H. RAYMOND, Chairman of the Local Committee, made a brief address of welcome, and explained what arrangements had been made for the reception of visiting delegates and for their entertainment in the city.

A long list of members-elect was then read and accepted.

PROFESSOR CHARLES A. LINDSLAY, of Yale College, read a paper by Dr. W. Thornton Parker, of Newport, R. I., entitled

### THE OVERSHADOWING OF OUR HOMES.

Houses overshaded are not healthful, however commodious or well built they may be. Too many trees near sleeping and living rooms are injurious and induce disease. A soil loaded with roots and shaded from the sun is unfit to live upon. Free drainage, abundant sunlight, and pure air in free circulation must be obtained by thinning out shade-trees, which are delusive ornaments and a dangerous menace. The nervous system, as well as general bodily health, suffers from a lack of sunlight. A National Board of Health should have authority to discipline summer resorts and other localities where health-seekers jeopardize their lives through neglect in such matters of hygiene.

In the discussion which followed, opinions quite opposite to those of the writer were expressed. Delegates from Washington and New Haven said that although their streets were thickly shaded, the rate of sickness was no greater than elsewhere. Cutting down trees would do more harm than good.

Dr. James F. Hibberd, of Richmond, Ind., read a paper on

CLOTHING IN ITS RELATION TO HYGIENE.

Considerable has been done to procure sanitary clothing for soldiers, sailors, and other government servants, but ordinary citizens have little regard for the varying requirements of the climate. Many dress too warmly to allow proper functions of the skin. The popular estimate of the hygiene of the skin is below its real importance. Interference with the physiological action of the skin endangers health, and is the primary cause of many constitutional disturbances. There should be established and maintained a power of resisting disease by avoiding overdress, and the consequent too great generation of heat in the skin, and also by periodical exposure of the surface of the body to low temperature. The clothing should be so arranged as to allow free circulation of air and proper ventilation of the exhalations of the skin, without too great loss of caloric in cold weather. Clothing that irritates the skin produces abnormal perspiration, and predisposes to peritonitis, rheumatism, and kindred ills.

Dr. Walker cordially indorsed the views of the paper, and substantiated them by his own experience. When children kick the clothing from their beds, it signifies that too much heat is being generated for their well-being.

The meeting then took a recess to inspect the

SANITARY EXHIBITION,

under the direction of Dr. A. N. Bell, of Brooklyn. There were presented in great abundance various food-preparations, medicines, disinfecting apparatus, specimens of sanitary plumbing, garbage-consumers, ice-machines, etc.

---

## Afternoon Session.

Dr. Jerome Walker, of Brooklyn, read a paper on the

CAUSES AND PREVENTION OF INFANT-MORTALITY.

The common belief that infant-mortality in this country has diminished of late years is not sustained by statistics. The death-rate might be reduced under favoring conditions, but these conditions will not be reached while the control of health-boards remains in the hands of mere politicians. A radical change must be made in this respect and in the better education of the masses. A large proportion of deaths in institutions for children is preventable, and the mortality may be lessened by giving the control of all medical and sanitary matters into the hands of reliable and responsible physicians.

Mr. Alfred F. White, C.E., of Brooklyn, then read a paper on the

RELATION OF THE DWELLINGS OF THE POOR TO INFANT-MORTALITY.

Statistics were given showing the need in this country of such institutions as the Peabody Association of London. The evils of crowding families in unhygienic apartments, with every opportunity for the spread of communicable diseases, are responsible to a great extent for the great mortality among infants. Scarcely fifty years ago there was not a tenement-house in New York, but they are now found not only in large cities but in rural towns, and growing up in all directions. They affect not only the health but the minds and morals of their occupants, and are a public danger. In London large sums of money have been expended in heroic measures to grapple with this evil, and the death-rate has been lowered to a point which twenty-five years ago would have seemed impossible. In 1888 the mortality in London was 15.99 per 1,000, while in New York it was 26.18; in Boston, 23.23; in Brooklyn, 22.72; and in Philadelphia, 20.70 per 1,000. These figures show abundant room for advance in obtaining conditions which shall assist to maintain health and prolong life. The study of the problem of housing the poor was begun over fifty years ago in London. The Improved Industrial Dwellings Company was one of the first societies to make a practical test. They invested £1,000,000 in buildings which accommodated 5,300 families, comprising 22,000 individuals. Abundant light and air are supplied to every room, and separate sanitary conveniences to each tenant. Stairways are provided only on the outside of the buildings, and there is no common interior shaft or any communication from floor to floor. Somewhat after the plan of these are the Tower Buildings in Brooklyn. In the city at large the annual deaths of children under five years average between 9 and 10 to 100, while in these buildings only 6 or 7 (according to the agent's figures). In the old-style tenements in New York the Board of Health figures show a corresponding rate of 11.4 per 100. In Brooklyn the records show no instance in which a contagious disease has been communicated to an adjoining apartment, above or below. Cholera infantum may be lessened in these buildings, in so far as the summer heat is alleviated by thorough ventilation from front to rear in every apartment.

DISCUSSION.

Dr. E. H. Bartley, of Brooklyn, spoke on the necessity of milk disinfectants, and attributed much of the disease of children to impurities in the milk.

Dr. Walker referred to a series of experiments made with the milk from cows fed at Prospect Park, on brewers' grain, from distillery slops, and from reliable dealers. Feeding cows on brewers' slops increased the supply of milk, but such milk putrefied quicker, and apparently without going through a stage of fermentation. Milk given by cows fed on pure hay was found to be the best.

Dr. Maxwell, of Florida, inquired why infantile diarrhœa was so rare in the South and so commonly fatal in the North. The death-rate from that cause in San Francisco was five, and in New Orleans seven, in ten thousand; while in Boston it was twenty-five, and in Chicago thirty-five, per ten thousand. Why is cholera infantum as common in some small towns and even in farm-houses in the Middle States, as in large cities?

Dr. McDonald, of Missouri, thought that cholera infantum is nearly always caused by the check to the nervous system in a sudden transition from heat to cold.

Dr. J. P. Thompson, of Kentucky, took an opposite view, and argued that the disease is always produced by indigestible food.

Dr. Staunton, of Ohio, and Dr. Clarke, of Buffalo, spoke of the necessity for disinfecting milk and seeing that the cows are judiciously fed.

Dr. George Homan, Secretary of the State Board of Health, St. Louis, Mo., then read a paper entitled

A SUGGESTED MINIMUM BASIS OF COMPENSATION TO LOCAL HEALTH OFFICERS.

The meeting then adjourned.

---

## Evening Session—Public Reception.

Dr. J. H. Raymond, of Brooklyn, presided and opened the meeting with a few words of welcome, congratulating the Association on its large membership—now over six hundred—and its good work in battling with disease. It has succeeded in preventing as well as in quelling epidemics. Its influence and teaching have subjected to scientific control nearly every form of pestilential visitation.

Hon. Alfred C. Chapin, Mayor of Brooklyn, in behalf of the city, welcomed the Association to Brooklyn as one of the most healthful cities of the country. The need of such work as this body performs is felt in healthful as well as diseased communities. As the health

of the city is due in part to the vigor and good constitution of its founders, so the promotion of the

HEALTH OF THE PRESENT GENERATION

will bear fruit in its descendants, and succeeding generations will be thankful for our efforts in securing their health. The medical profession and the State are mutually dependent in advancing the public weal, and should work together to make good laws and induce correct habits among the people.

Dr. Alex. Hutchins, of Brooklyn, then delivered the

ADDRESS OF WELCOME

in behalf of the medical profession. He invited the Association to the hospitals and dispensaries, the medical college and laboratories, the libraries and the homes of the city. He referred to the comprehensive National Sanitary Exhibition of Sanitary Appliances. He reviewed the growth of measures for the prevention of disease and the development of public health legislation.

THE PRESIDENT'S ADDRESS

was then delivered by Professor Hosmer A. Johnson, M.D., of Chicago. He stated that the purpose of the Association was not only to interest and secure the services of physicians, but all other scientific men and the public generally. The necessity for such organizations in behalf of the public health is great, and their importance should be more recognized. A National Department of Health is more needed than the Department of Agriculture, and a Department of Vital Statistics more than a Department of Animal Industry. Within the memory of many in the audience, there was not an efficient board of health in the world. To promote hygienic living and sanitary surroundings, and thus reduce the causes of disease, it is necessary to disseminate scientific knowledge. Plague and pestilence have owed their origin and spread to ignorance and neglect of the laws of health. Comparisons show what science has done for public health in recent years. Legislative enactments and police regulations are required for protection, and have been stimulated by bitter experience with epidemics, and often framed in times of danger. They are thus too often provisional and insufficient. They should be made in times of safety. There should be a removal or destruction of the evil agencies which threaten society. It is the province of this Association to inform the public in regard to proper sanitary precautions. A health officer is as much needed in every community as a justice of the peace or a constable. The collection of vital statistics is also important, and every town and village should have proper registration of all births, deaths, and cases of communicable disease. There should also be a national Board of Health, with the power and means for attaining its much needed ends.

The matter of proper quarantine should also receive more public attention and more complete legislation with regard to zymotic diseases. Typhoid fever was formerly regarded as a "visitation of Providence." The time is coming when such disease will be considered as due to crime.

A death from typhoid fever now means not so much a dispensation of Providence as it means foul water, foul food, or foul air. A city is decimated by a pestilence, and it is found that its foundations are honeycombed with cesspools, and its drinking-water is diluted sewage. The judgments of God, in the light of these revelations, become no more mysterious than the pains of the child that thrusts its finger into the flame only to feel the terrible infliction that follows. There has come to be an enthusiasm in the medical profession on this subject, which has made itself felt in various ways. This zeal has communicated itself to the public. An intelligent foundation has been laid for sanitary reforms.

The average length of life now is forty years, but an intelligent regard for the laws of health in the community ought to add another forty years. There are more deaths annually from preventable diseases than from any one visitation of cholera or any other dreaded epidemic.

The death-rate of twenty-six of the principal cities of America, with a population of 9,873,448, is 20 per 1,000. It is morally certain that this rate could be reduced by means and methods now known to sanitary science to 16 per 1,000, and probably still less than that. The death-rate for London for the year 1888 was 18.5 per 1,000. This can be still further reduced. That of New York and Brooklyn for the same year, taken together, is 25.5 per 1,000—New York, 25.9; Brooklyn, 23.7. The death-rate of these two cities, if reduced to that of London, would secure a saving of 7 per 1,000, or annually 15,986 lives. These lives are public wealth. But this is not all. For one death annually two persons are sick during the entire year, or, in other words, there are two years of disabling sickness to one death; 31,972 years in New York and Brooklyn of sickness—preventable sickness—annually. The value of these years of sickness cannot be reached with accuracy, but the wages lost on account of sickness, the cost of care and maintenance during sickness and convalescence, and the money value of the lives destroyed, considering them only as machines, will, in New York and Brooklyn, reach annually into the millions.

Rev. Dr. Richard S. Storrs, President of the Long Island Historical Society, next made a brief address. He alluded to the relations of amity and helpfulness which should exist between the clergyman and physician. *Health* and *holiness* are derived from the same root, which signifies wholeness. There is no conflict between science and religion. One throws light on the origin, the other on the destination of man.

Hon. Seth Low, the president-elect of Columbia College, expressed sympathy with the work of the Association. Brooklyn is approaching a new problem in sanitary matters. Built at first on high land sloping to the bay, the city easily secured good drainage. Now the growth of the city eastward occupies land sloping but slightly toward the sea; and the drainage, instead of pouring into a swiftly flowing tide, finds its way to landlocked basins. The question of proper sewerage and the disposition of sewage forms one of the most important problems before this Association. A visit to the sewage-farm in Paris was very instructive, as showing this waste material converted into a useful product.

---

Second Day, Wednesday, October 23d — Morning Session.

Dr. John S. Billings, of the U. S. Army, Washington, D. C., read a paper entitled

THE UNITED STATES CENSUS IN ITS RELATION TO SANITATION.

He emphasized the importance of the collection of vital statistics. Many do not regard this as so important as other work in behalf of public health. In order to convince the press and the community that the work of a Board of Health is necessary, you must produce constant, undeniable evidence; and this evidence must be mainly death-rates, to which should be added all the sickness-rates obtainable. To do this there must be a complete registration of deaths and births, and an enumeration of the whole population. Before this Association meets again the Eleventh United States Census will have been taken, and its methods and results are of great interest to all sanitarians. One of the most important questions to be settled before the census is taken is what shall be the boundaries of the special districts of the city for which a separate statement of the population is desired. In some cities the wards form fairly satisfactory districts for the purpose, and where this is the case it makes the problem very easy. But in many cities these divisions bear no proper relation to different sanitary conditions. Therefore in about a dozen of our large cities it is proposed to make a systematic division of the area into sanitary districts having special relations to altitude, character of habitations, or of population, etc., and to have special death-rates calculated for each of these districts. This is

being done in conference with the health authorities of these cities, and it is hoped that in this way some very interesting data will be obtained which will serve as a foundation for sanitary work in the future.

To make the statistics as correct and useful as possible, all deaths occurring in hospitals should be charged to the ward or district of the city from which the patient was taken to hospital, when this can be ascertained. Otherwise the death-rate in the ward in which the hospital is located will be too high and in the other districts it will be too low. The birthplace of the parents of the decedent should be also reported. Moreover, it is very desirable that in all cases of deaths of colored persons it should be stated whether the decedent was black or of mixed blood, such as mulatto or quadroon. One of the most important questions in the vital and social statistics of this country relates to the fertility, longevity, and liability to certain diseases of those partly of negro and partly of white blood, and the only way to obtain data on this subject is through the registration of vital statistics. For all cities of ten thousand inhabitants and upward it is proposed to collect as complete information as possible with regard to altitude, climate, water-supply, density of population, sewerage, proportion of sewered and non-sewered areas, and other points bearing on the healthfulness of the place which will permit of interesting comparisons with the death-rates. The cordial co-operation of all physicians and sanitarians is solicited in making the data of these reports accurate and complete. It is desired to make these vital statistics an unanswerable argument in favor of systematic public sanitary work and of the granting of State and municipal funds necessary for maintaining such work.

Dr. J. N. McCormack, of Kentucky, offered a resolution recommending that the sanitary authorities of Mexico and Cuba be invited to send representatives to the future meetings of the Association. This was referred to the Executive Committee under the rules.

Professor Lindsay then read the paper prepared by Dr. Ezra M. Hunt, Secretary of the State Board of Health, Trenton, N. J., entitled

THE PREVENTION OF PHTHISIS PULMONALIS AND METHODS FOR ITS LIMITATION.

The paper criticised the writings of those who regard the infection of phthisis pulmonalis as exclusively due to inhalation of the dried sputa of this disease. The theory was advocated that the breath of a consumptive patient is capable of carrying the contagion.

Discussion of the paper was postponed, and after a brief intermission, for business notices, Dr. W. M. Smith, Quarantine Officer of the Port of New York, read a paper, illustrated by stereopticon views, on

IMPROVEMENTS AT THE NEW YORK QUARANTINE STATION.

He began with the history of the earliest establishment of a quarantine station in New York, and went on to describe how the present grounds were taken up for that purpose. Illustrations of the ground plans of the buildings were thrown on the screen, and the speaker explained how the drainage and sewerage of the island were constructed; how patients suffering with contagious diseases were enabled to enjoy an outing without coming in contact with any of the other patients. Then the methods of disinfecting were explained, and views of the various chambers used for the purpose were shown.

The Association then adjourned and proceeded to take an excursion to the Quarantine and East River hospitals, accompanied by Dr. Smith.

---

Evening Session.

Dr George M. Sternberg, U. S. Army, of Baltimore, Md., gave an account of

RECENT RESEARCHES RELATING TO THE ETIOLOGY OF YELLOW FEVER.

The investigations were made in Havana, between the middle of March and the first of September, 1889. Ample material has been obtained for a thorough research by modern culture methods. Thirty autopsies have been made in typical cases of yellow fever. The cultures obtained require further study and extended comparative research before any definite conclusion can be reached as to the specific etiological relation of one or other of the micro-organisms found in yellow-fever cadavers, principally in the intestine. One method followed in the entire series of cases was the preservation of a piece of liver or kidney in an antiseptic wrapping, by which the exterior was sterilized and the entrance of germs from without prevented. Such a piece, after forty-eight hours in the laboratory, appeared fresh and had no odor, but when cut, was found to contain various micro-organisms. The cut surface had an acid reaction. The bacilli were of various species, and corresponding with those found in the contents of the intestine. No satisfactory evidence has been obtained, up to the present time, that any one of these is the veritable yellow-fever germ. One of the most constantly found of these micro-organisms was a large, motionless, anaerobic bacillus, resembling that of malignant œdema. This, and others found in a less number of cases, were present in small numbers at death, and in a large proportion of cases the result of an examination made immediately from fresh liver-tissue was negative. Material from a piece of liver, kept as above, and containing micro-organisms, is very pathogenic for guinea-pigs when injected subcutaneously in small quantities, while the fresh tissue may be injected in considerable amount without noticeable effect. The micrococcus of Freire has not been found in any cultures of this series, and the bacilli of Finlay and Gibier have not generally been found in the tissues of yellow-fever cadavers.

Dr. Theobald Smith, of Washington, read some

PRELIMINARY OBSERVATIONS ON THE MICRO-ORGANISM OF TEXAS FEVER.

Cultures have been made from the spleens of animals who died of Texas fever, and a variety of bacteria found. A variety of experiments led to the discovery of an organism within the red blood-corpuscles. The intra-globular bodies found are round or oval and nearly colorless. There is usually one, but two or more may be found in one corpuscle. Stereopticon views of the organisms found were shown upon the screen.

This was followed by a paper by D. E. Salmon, D.V.M., Chief of the Bureau of Animal Industry, Washington, entitled

SOME GENERAL OBSERVATIONS ON TEXAS FEVER.

The resemblance in the characteristics of yellow fever in man and Texas fever in cattle was noticed. Each disease has a permanently infected and well-known district which is its home. The contagion of both diseases is carried not by the sick, but by the healthy. Natives in the infected districts have a certain immunity from disease, while non-residents entering the locality will contract the fever. Both diseases, when carried north of their home, require a period of warm weather for development. Neither contagion survives a winter of snow and frost beyond its home. Both diseases are accompanied by an inflammation of the liver which causes yellow discoloration of the tissues, and in both hæmaturia is seen. These points of similarity may indicate that the germs have a similar nature, but the facts are given as a coincidence.

Edward Atkinson, LL.D., of Boston, Mass., read a paper on

THE ART OF COOKING.

A form of oven heated by an oil lamp, with great saving of heat and fuel, was shown, and food prepared before the audience.

The meeting then adjourned.

---

Chloralanide is the name of the latest new hypnotic. It is a combination of chloral and formamide, and is given in doses of 15 to 60 grains.

## AMERICAN DERMATOLOGICAL ASSOCIATION.

*Thirteenth Annual Meeting, held at Boston, Mass., September 17, 18, and 19, 1889.*

FIRST DAY, TUESDAY, SEPTEMBER 17TH — MORNING SESSION.

THE President, DR. J. E. GRAHAM, of Toronto, Canada, called the meeting to order at 10 A.M., and after a short executive meeting, in which reports were read and committees appointed, Dr. Graham, as presiding officer, made

### THE OPENING ADDRESS.

He referred to Boston as a city which had always been a centre of activity in dermatological matters. The Harvard had been among the first schools to establish a chair of dermatology. The earliest works on the subject were published here. "Brief Notes on Small-pox and Measles" was the title of a book published here as early as 1677. The hope was expressed that the present gathering, in this birthplace of American dermatology, would be a profitable and pleasant one. The importance of greater attention being paid to sanitary matters was dwelt upon, and the possibility of preventing the spread of many infectious and contagious diseases by the enactment of sanitary laws. In two diseases, not themselves dangerous, but extremely disagreeable, viz., scabies and tinea tonsurans, much could be done in the matter of eradication and prevention by appropriate measures. Reference was made to Dr. White's recent paper, in which an increase of scabies in Boston was noted, and the inspection of children in public institutions advocated by it was indorsed. Tinea tonsurans, when once firmly implanted in an asylum or school, is with the utmost difficulty eradicated. He referred to a provincial town in Canada in which inspection had resulted very favorably. The subjects of syphilis and leprosy, as great menaces to the public weal, were then taken up. The evil resulting from the first was very wide-spread, while the attempts to eradicate it, or check its progress, were few, spasmodic, or of local character. In other countries, where laws had been enacted relating to syphilis, the results had not been very encouraging. Denmark and France were especially spoken of, where imperfect registration defeated the objects of the enactments. One fault in this country lies in the imperfect knowledge of the disease acquired in our medical schools. Students are too apt to think, if they intend practising in the country, that they will not be called upon to treat the disease. This is a great mistake; unfortunately, it is to be found in all sections, and affecting all classes. Absolutely free treatment in all hospitals and public institutions was advocated. Separate wards and hospitals should be set apart where these patients could be treated with consideration, and inducements should be held out to them to enter. Great danger threatened the community at large, and public moneys should be freely spent for this object. Examination of wet-nurses was important, as they were very frequently found affected. Periodical examination of soldiers and sailors should also be made. Care in vaccination, circumcision, and proper instruction of youth were prophylactic means not to be neglected.

The spread of leprosy has recently excited much attention. Dr. Morrow's paper has caused discussion of the subject. Leprosy is contagious, in the wide acceptation of the term. Each leper, by direct or indirect transmission, is a focus of danger. Inoculation has become a well-established fact. The germs may be introduced by food, or possibly by inhalation. Instances of this are not proven, but we are not in a position to deny its weight. Hereditary transmission is not now so much thought of as hereditary predisposition. There has been no decided increase here, till of late years. Development of the germs seems to depend on the condition of the individual with whom they come in contact. Immunity here depends on manner of living rather than on any peculiar idiosyncrasy. The slow spread here is explained by the fact that those attacked are of other than Anglo-Saxon race. It is possible that an Anglo-Saxon leper, living among Anglo-Saxons, would prove a source of infection. If once started it will be impossible to control it. The facts favorable to its extension here are, that it exists in every quarter; we have it on every side. There is no danger of a rapid spread, but of an insidious progress until it becomes formidable. The Government should take measures at once to prevent its spread. The speaker advocated sending back cases to their own country; keeping suspected cases under surveillance; and segregation. It is difficult to secure separation, as the individual is unwilling to enter a settlement. Asylums should be made desirable places of residence. Dr. White advocated, in 1874, at the first meeting of this Association, a consideration of questions of national importance. Up to that time there had appeared no cause of alarm in regard to leprosy, but at that time he thought it by no means improbable that a foothold might be obtained. Certainly in many States and cities too little attention has been paid to such sanitary considerations. The rule to hold the meetings of this Association in large centres of population, where rare skin diseases could be presented, should be carried out.

The first paper read after the President had declared the Association open for business was one by DR. F. B. GREENOUGH, of Boston, on

### HERPES ZOSTER,

based upon personal observations extending over sixteen years, in which time two hundred and fifty-five cases of the disease had been treated out of a total of seventeen thousand seven hundred and forty-one cases of skin disease. The average age had fallen between ten and fifteen years, and the largest number of cases in any cycle of five years of life were found between these years, the number being fifty-nine. The youngest patient was three months of age, and the oldest was aged eighty-eight. The neurotic origin of herpes zoster has been pretty generally conceded, but as it is observed with somewhat greater frequency in the spring-time, we must assume that certain unknown factors influence the eruption. The situation of the lesions, as recorded, shows that the costal region is affected in about fifty per cent. of the cases, the facial and cervical in about eight per cent., and the abdominal in about six per cent. The older the patient the more likely was it that pain would be a prominent symptom. In nineteen cases the pain was very severe, and the average age of these patients was forty-four years. In several instances the vesicles appeared to pass beyond the median line on the back, but in each instance careful examination showed that there was a slight curve of the spine to account for the appearances. One patient had a double zoster of the nose. Two cases showed lesions upon the fingers at the terminal ends of the brachial nerve. The reader had observed a herpes progenitalis extending upon the shaft of the penis which closely resembled a zoster.

As to treatment, the abortive method is not favorably looked upon. It is advised to leave the vesicles alone as much as possible, and to prevent their rupture. Diachylon plaster, permanently applied to the affected region, has seemed to do as much good as anything. No benefit was derived from internal antirheumatic remedies.

DR. FOX, of New York, said that upon close questioning violence will often be found to have preceded the outbreak. Internal remedies, in his experience, were without effect, and most of the methods of treatment in vogue were extremely unsatisfactory. He had given up collodion applications. Much benefit could result from galvanism.

DR. ROBINSON, of New York, could not regard the disease as a neurosis, but looked upon it as an infectious process.

DR. ZEISLER, of Chicago, spoke of the occurrence of zoster soon after the internal use of arsenic. In one case

recently observed it appeared after Fowler's solution had been increased up to thirty-drop doses.

Dr. Bronson, of New York, said there was an unsolved mystery about zoster. It does not depend upon time, locality, or age. Its occurrence but once in a lifetime supports the theory of infection. He has secured good results from the application of gutta-percha dissolved in chloroform.

Dr. Sherwell, of Brooklyn, spoke of three cases he had observed in which a zona ophthalmica was attended with an eruption upon the ala nasi of the same side. He employed occlusive dressings, galvanism, and had also given internal remedies with seeming good effect.

Dr. Hardaway, of St. Louis, spoke of the possibility of chronic zoster, and related a case of herpes upon both sides of the neck which had persisted for months, and showed the usual signs of zoster. Ten or twelve cells of an ordinary galvanic battery usually gives relief from the pain, but in some cases, at least, there is present an element of imagination. Protective dressings and collodion are much superior to any form of ointment.

Dr. Bulkley, of New York, said the proportion of cases in New York was similar to that given by the reader of the paper. He has seen a zoster in a patient upon whose body were the signs of a previous attack. He would regard it as the result of a simple neuritis, due at times to cold and at times to injury, and had often seen it develop in patients under arsenical treatment. Great relief of pain is secured by the galvanic treatment, and at times it appears to have an abortive effect. He prefers a tight-fitting bandage, under which the skin and lesions are thickly dusted with starch powder, to any other dressing.

Dr. Howe, of Boston, said the collodia dressings had given him little satisfaction, excepting in the erythematous form. Galvanism has, on the other hand, given great relief. As a dressing he applied thin strips of cork above and below the eruption, and maintained them in place by adhesive strips. The lesions themselves are best dusted with some bland powder.

Dr. Klotz, of New York, referred to the paper on this subject read by Kaposi at the Prague Congress, in which epidemics of the disease were reported. He maintained that the affection in which recurrence took place differed from the ordinary zoster. He himself could not accept the infectious theory. He had seen double zoster of the face. Two personal cases were related in which deep scars were left. Both patients were syphilitics, and the speaker thought this often the cause of scars.

Dr. Morrow, of New York, had seen the eruption follow a blow after a short interval. He had also observed the lesions of zoster extending down over the toes. In one case the pain was localized in the knee. Many things point to its infectious nature, and the fact that it occurs after injury does not disprove the theory. A hot-water bag to the spine often gives relief from the pain.

Dr. Robinson said a zoster-like eruption could follow an injury, but this did not prevent a subsequent true zoster from appearing, and making it seem like a recurrence.

Dr. Graham, of Toronto, Canada, spoke of a fatal case in a boy under his care. Febrile symptoms and pain preceded the eruption by three days. On the fourth there was severe pain on the opposite side of the face, and on the fifth the patient died. Autopsy showed intense inflammation of the Gasserian ganglia on both sides. A bacillus of unknown name and nature which was found in the ganglia was demonstrated before the Association.

Dr. Greenough, in closing, said that in one case he had mentioned the lesions were limited to the finger and thumb.

Dr. Heitzmann, of New York, then read a paper on

### MICROSCOPICAL STUDIES OF MALIGNANT TUMORS OF THE SKIN.

The basis-substance of the fibrous connective tissue of the derma is living, and capable of proliferation. In dermatitis we observe in the earliest stages an augmentation of the living matter leading to the appearance of inflammatory corpuscles. A breaking asunder of the inflammatory corpuscles leads to the formation of pus-corpuscles. In the production of tumors the tissue of the derma invariably falls back into its protoplasmic condition, with new-formation of medullary or indifferent corpuscles from which a tissue originates. The newly formed tissue may remain in an embryonal or medullary condition, as in sarcoma. He had seen all varieties of sarcoma in the skin, but thought it necessary to make but two varieties: *Globo-myeloma*, identical with Virchow's "round-celled sarcoma," and *spindle-myeloma*, or spindle-celled sarcoma. Sarcoma of the skin does not often ulcerate; the tissues over them become thinner and thinner, and finally break through, and a superficial ulceration may take place. The new-formation of myeloma-corpuscles takes place from the protoplasm between the bundles of connective tissue and also from the basis-substance of the bundles themselves. All epithelial structures will sooner or later disappear when myeloma comes in the skin. When the growth proceeds very rapidly they will be transformed into myeloma-corpuscles. Two views are held regarding cancer: 1. That it invariably starts from epithelia. 2. That the connective tissue may furnish material for it. Primary cancer, according to the reader, may appear in places where there is no trace of epithelial formation. Small glistening bodies or corpuscles in groups were shown under the microscope, which the author regarded as the pre-stage of cancer and an almost sure indication of the extension of the process if found beyond the tumor; or, if found after operation, recurrence could be predicted.

Dr. Robinson agreed with the views respecting the structure of the derma. He made a broad distinction, however, between tumors proper and sarcomata, which he regarded as an infective process. At the point of development there is, of course, a dermatitis and connective-tissue new-growth. He did not think epitheliomata could exist without previous epithelial tissue, and he cannot now admit that that connective tissue returns to embryonal tissue and then becomes epitheliomatous. For example, he had never seen epithelioma primarily develop in a lymphatic gland.

Dr. Heitzmann said he could admit that when it starts, in the early stage, we could not tell sarcoma from inflammation, but the former goes on to the formation of tumor while the latter stops. His view—that epithelioma could develop from other than epithelial tissue—was not yet accepted in this country, but he thought it would be.

Dr. Morrow, of New York, read a paper entitled

### THE DIAGNOSIS OF LEPROSY.

The growing interest in this country in the subject of leprosy; the sad fate of Father Damien, which had directed the attention of the whole world to the disease; and the lack of sufficient clinical descriptions in the majority of text-books, had led the reader to consider some points in the differential diagnosis. Most authors of text-books have not been sufficiently familiar with the characteristic and pathognomonic features of the disease from their own clinical observations. During the reader's sojourn in the Sandwich Islands he had had an excellent opportunity to study the diagnosis in many cases, not only of those well known to be lepers, but also in suspected cases under government supervision. In the tubercular form the prodromal signs possess but little value, and show nothing characteristic. They are, however, of value in a retrospective sense. In the macular form the lesions are not pathognomonic, and are liable to be mistaken for syphilis, erythema multiforme, etc. Tubercular lepra and syphilis also bear the closest resemblance to each other. Nodules grouped upon an infiltrated base may also be mistaken for lupus. The bacillus occurring in leprous tissue, and nowhere else, is of the utmost importance in diagnosis. Hyperæsthesia is first present in the rosy patch

of the early macular form, but as the patch clears up in the middle, anæsthesia takes its place. Pigmentation may be present from the first, causing a marked resemblance to chromophytosis, but there is no scaliness. In lepra the depigmented spots are more grayish than in leucoderma. Pemphigoid blebs are sparser and more superficially situated than in ordinary pemphigus. The plantar ulcer, frequent in the tropics, bears a close resemblance to *mal perforans*. Many neurotic diseases are simulated: Progressive muscular atrophy, chronic arthritis deformans, etc. Unilateral development of lepra is not uncommon. In the Sandwich Islands one-third of the cases were anæsthetic, and two-thirds of the mixed type. Many photographic illustrations were shown.

DR. BULKLEY asked if other lesions were present in the case resembling perforating ulcer of the foot.

DR. MORROW said no, but that the patient had since then shown other well-marked signs, and was now at the leper settlement at Molokai.

DR. GRAHAM spoke of a case of perforating ulcer seen at Tracadie, in a leprous woman seventy-one years of age, who had never been in the habit of going barefoot.

DR. JACKSON, of New York, then presented

A CONTRIBUTION TO DERMATOLOGICAL BIBLIOGRAPHY,

consisting of a catalogue comprising over three thousand titles to works on skin diseases, and more than twelve hundred on syphilitic subjects, which will be published in pamphlet form.

THE OCCURRENCE OF PRURIGO IN AMERICA

was the next paper, read by DR. ZEISLER, of Chicago, who showed that while the existence of the disease in this country had been often and in many quarters denied, it still existed in some localities here to almost as great an extent as in Vienna. Twelve cases have been seen by the reader during the past year out of a total of one thousand three hundred and seventy cases of skin disease. He accounts for the fewer cases generally seen in this country by the fact of improved facilities for bathing and better sanitary surroundings, to say nothing of difference in climate.

Dr. Taylor had seen two typical cases here. The testimony of almost all members who spoke went to show that prurigo is not often seen in this country, although, with scarcely an exception, the gentlemen had observed and studied the disease in Vienna, and were familiar with it.

A PRURIGO PATIENT

was presented by Dr. Tilden for DR. WIGGLESWORTH, of Boston. A boy born near Boston, about fifteen years of age, had been under his care for some time. Upon examination, Dr. Zeisler and several others pronounced it a typical case of the disease.

DR. FOX thought the only essential difference between such a case and one of eczema was the question of duration.

DR. ALLEN spoke of a case quite similar to the one presented, now under treatment, which he had regarded as a true prurigo.

DR. BULKLEY thought many such cases had been classed as eczema in this country.

DR. ZEISLER made the point that in papular eczema the face, hands, and scalp were always affected, while in prurigo they are free. Mild cases do get well, even in Vienna, and especially since the beta-naphthol treatment has been employed.

DR. SHEPPERD, of Montreal, read a paper entitled

TWO CASES OF ECZEMA MERCURIALE,

describing an eczema as the result of the application of mistura ammoniaci cum hydrargyra, or, as it is known in Canada, "Scott's Dressing." It had been used as a local dressing, spread on sheepskin, in treating synovitis. An erythematous eczema, at first local, soon spread to the face and genitals, and resembled rhus-poisoning.

DR. MORROW said it is not unusual to see drug-eruptions persist long after the drug is removed.

DR. GRAHAM had seen the same results from bichloride dressings.

DR. KLOTZ read a paper entitled

CLINICAL OBSERVATIONS ON INJECTIONS OF INSOLUBLE MERCURIAL SALTS IN SYPHILIS.

The reader was aware that in this country the treatment was considered one for emergency, and was not looked upon favorably as a method for general use. Little objection had been found on the part of any of the patients, and many were much pleased with it.

Two hundred and ten intramuscular injections had been made upon twenty-three different patients. Calomel, the yellow oxide, and the salicylate of mercury were all tried, but the yellow oxide was most used, in the strength of 1 to 30 suspended in water, olive-oil, or vaseline. An average of ten injections was made for each patient. Two abscesses were produced, both following an injection of calomel suspended in water. None followed when it was suspended in oil. Affections of the skin were almost always favorably impressed by the injections, and the results in general were so encouraging that the reader does not feel inclined to give up the method.

DR. TAYLOR thought it would not often be necessary to resort to intramuscular injection; still, the method might be good for certain emergency cases. There are too many dangers to permit of a permanent adoption of the method.

DR. MORROW regarded it as a reserve treatment where others are contraindicated.

DR. ZEISLER did not think the method applicable to cases in general, or practicable.

DR. SHERWELL thought the dosage inexact.

DR. BRONSON thought it a scientific means of treatment the application of which we had not yet fully mastered.

DR. HEITZMANN had obtained painful nodules when the greatest antiseptic precautions were employed.

DR. KLOTZ said abscesses were more frequent in beginning the injections, but as experience is acquired the danger grows less. The good qualities of the method far outweigh the bad ones.

(To be continued.)

## MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

*Fifteenth Annual Session, held at Evansville, Ind., September* 10, 11, *and* 12, 1889.

DR. GEORGE F. COOK, OF INDIANAPOLIS, PRESIDENT, IN THE CHAIR.

THE Secretary, Dr. R. L. Thompson, of St. Louis, and the Chairman of the Committee of Arrangements, Dr. A. M. Owen, of Evansville, were everywhere. The attendance was good, for this "side-tracked village in the pocket of Indiana."

The President, owing to the immense programme of about one hundred papers, begged to be excused from a formal address, and made only a few opening remarks.

The Committee on Nominations, by their Chairman, Dr. I. N. Love, of St. Louis, Mo., reported as follows: *President*—Dr. Joseph M. Matthews, of Louisville; *First Vice-President*—Dr. C. R. Earley, of Pennsylvania; *Second Vice-President*—Dr. T. B. Harvey, of Indianapolis; *Permanent Secretary*—Dr. E. S. McKee, of Cincinnati.

Invitations for holding the next annual meeting were received from Excelsior Springs, Mo., Chattanooga, Tenn., Cincinnati, O., and Louisville, Ky. Louisville was chosen, and September 9, 10, and 11, 1890, appointed for the meeting.

The newly elected President was escorted to the chair, and made some appropriate remarks.

ANTIPYRETICS, ANALGESICS, AND HYPNOTICS,

was the title of a paper by DR. I. N. LOVE, of St. Louis. He discussed quinine, opium, antipyrine, acetanelid, bro-

mides, urethran, and exalgine. We should guard carefully against the possibility of self-drugging, and with this end in view he thinks it the physician's duty to dispense himself all analgesics and sedatives. He can thus limit the amount taken and, if desirable, keep from the patient a knowledge of the dosage. All the derivatives of the aromatic series, being antiseptic, antipyretic, and analgesic, are of great value to us in our battles with disease. Acetanelid, in his experience, stands at the head of the list, and exalgine has been so satisfactory as to justify a more extended use.

DR. S. BISHOP, of Chicago, read a paper entitled

THE ABORTION OF ACUTE NASAL CATARRH.

If the case was a severe one he administered half a grain of morphia and one one-hundredth grain of atropia, lessening the dose if the attack was a light one.

"A Simple Method of Treating Fistula in Ano" was the subject of a paper by Dr. Joseph M. Matthews, of Louisville. This paper created an interesting discussion, which was taken part in by J. M. Murdock, of Pittsburg, H. H. Grant, of Louisville, Archibald Dixon, of Henderson, and W. H. Wathen, of Louisville.

"The Myopic Eye" was the brief title of a pointed paper by Dr. Dudley S. Reynolds, of Louisville. The doctor related a series of interesting cases. He indicated the three principal agents for the arrest of the progressive myopia: Eserine, pilocarpine, and iridectomy. That the myopic eye is always an unsound eye should be constantly borne in mind. That the myopic state of refraction is always the result of abuse should be universally known, for it concerns the whole human family.

"The Treatment of Strangulated Hernia" was the title of a paper by Dr. W. H. Meyers, of Fort Wayne, Ind. He advised to shun opium, and scolded at delay. If the patient is seen within a few hours of the accident, we may employ taxis with no other interference for six or eight hours as the extreme limit. Otherwise this treatment should be limited to minutes, and the operation performed.

"The Accoucheur and his Forceps" was the subject of an essay by Dr. A. S. Bemes, of St. Louis.

DR. J. A. LARABEE, of Louisville, read a paper entitled

INFANTILE THERAPEUTICS.

He thought the old therapeutic furniture fitted remarkably well the new house with its microbian windows. He thought infantile therapeutics should include an infinite knowledge of hygiene and of hydrotherapy. Water is entirely too common to command respect. If it could be sold in small quantities at fabulous prices it would be better thought of. He often found it necessary to use a slight amount of deception to induce the use of water. He discussed endermatic, hypodermatic, and epidermatic medication, also the treatment of diphtheria.

DR. H. C. DALTON, of St. Louis, Superintendent of the City Hospital, read an interesting paper entitled

IS SENN'S GAS-TEST INFALLIBLE AND ALWAYS DEVOID OF DANGER?

He reported a case of gunshot wound of the abdomen, the ball passing into the thorax in the left axillary line, between the seventh and eighth ribs. There were no symptoms of abdominal injury, but, from the direction of the ball, he suspected that the abdominal cavity had been penetrated. He resected three inches of the seventh rib and found a hole through the diaphragm, three inches from the thoracic wall. He introduced a glass tube and applied the gas-test, but received negative results. Laparotomy was not performed. The patient came near dying from interference with respiration due to the enormously gaseous-distended intestines pressing upon the diaphragm. At the autopsy, eighteen hours after death, two holes were found in the greater curvature of the stomach four inches below the cardia, the hole of exit being a half-inch below hole of entrance. The lower third of the stomach was filled with semisolid food which had securely plugged up the bullet-holes during the administration of the gas and prevented its escape into the peritoneal cavity, thus accounting for the failure of the test.

He concluded, if semisolid food would cause the test to fail, semisolid fæces would do the same thing. and hence the claim that the test is infallible is untenable.

He also reported a case in which the test gave affirmative results, the gas escaping and igniting freely. Laparotomy was performed, and twelve holes were closed by the Lembert suture, two in the cæcum, six in the small intestines, three in the mesentery, and one in the hole of entrance. Owing to the gaseous extension, difficulty was experienced in returning the intestines to the cavity and closing the wound. In the attempt, the firm pressure used caused the holes to burst in several places, flooding the peritoneum and obliging the peritoneal toilet to be done *de novo*. He thinks this, together with the excessive gaseous pressure upon the diaphragm after the closure of the abdomen, adds to the shock, and hence he argues that the method is not devoid of danger. The patient died eighteen hours after the operation.

DR. ALEXANDER B. SHAW, of St. Louis, read a paper entitled

RESULTS OF SUSPENSION IN THE TREATMENT OF AFFECTIONS OF THE SPINAL CORD BY THE SHAW APPARATUS AND TECHNIQUE.

He began a series of experiments, June 16, 1889, with the apparatus devised by himself, for suspension in affections of the spinal cord. After personally suspending a number of patients every two or three days for several weeks, he turned the cases over to two assistants, who continued the treatment after the technique of Dr. Shaw. A report from them at the end of a little more than two months, refers especially to three cases, though in all ten have been receiving the treatment. Two of these patients were affected with tabes dorsalis; the other, with cerebro-spinal sclerosis.

CASE I.—German watchmaker, aged thirty-two, previous health fairly good; dates present illness from a burn received over left half of body, which confined him three months to his bed. After this he noticed difficulty in walking, until when he came under the treatment he was unable to walk without assistance. He appeared far advanced in the second stage of the disease. The greatest change is in his locomotion; he is now able to walk all about the institution, climb stairs, and a decided mental change is apparent. There seems an extension of at least five inches in the length of the neck in the suspension of this patient. There is some atrophy of the posterior cervical muscles. The backward bending of the knees, particularly marked in the beginning of treatment, is much lessened.

CASE II.—German tailor, aged sixty-six. No history of this patient, excepting some rheumatic ailment several years ago. He was able to walk with the use of a cane when he first came under notice, but was in frequent danger of falling. He was troubled by "girdle pains," which have lessened since suspension. On account of his weight he can stand treatment but a short time without great fatigue. From a state of almost utter helplessness he has so improved that he was able to walk into the city (six miles), remain several days, and walk back again. During an attack of acute diarrhœa he was unconscious for several days. After consciousness was restored there was such marked hyperæsthesia that scarcely the slightest touch could be borne on any part of the body. He says his eyesight has been improved; rheumatic pains less, and defecation and urination now normal.

CASE III.—Cerebro-spinal sclerosis. Englishman, aged forty seven, first noticed ailment in 1880; been under almost constant treatment from different physicians since. When suspension was begun, patient had difficult urination. There was a decided tremor when any co-ordinate movement was attempted, and placing fluids to his mouth was often impossible. Speech was defective; power of locomotion somewhat impaired, *i.e.*, ataxic. Decided im-

provement has been experienced in several respects; urination is now normal as to frequency, and he is not disturbed by tenesmus or burning sensations. When first received there was transverse and vertical nystagmus; now he says he can see farther, and there is not so much oscillation. He is able to articulate more distinctly, and can hold a vessel filled with water quite steadily.

Dr. E. S. McKee, of Cincinnati, read a paper entitled

STERILITY IN WOMAN; ITS ETIOLOGY AND TREATMENT.

The author found the subject a difficult one. He thought the most common cause of sterility was intra-uterine disease, and chronic endometritis its general manifestation. Inflammations of the pelvic peritoneum and of the parametria or their consequences are a frequent origin. Three things must be determined: Are spermatozoa in the semen? Do they get into the utero-cervical canal? Do the vaginal secretions poison the spermatozoa? Sterility in man must be eliminated before seeking the causes of childless marriages in the wife. Gross claims that one out of six sterile marriages is the fault of the husband, and Kehrer claims one-third, and the cause of the barrenness as gonorrhœa. The habits of the wealthy diminish fertility, while those of the poorer classes seem to favor it. The injurious effect of excessive fat in women, as regards childbearing, is generally admitted. The prospects of offspring will depend more on the menses than the flesh, amenorrhœic fat women being usually sterile. The prevalence of spasmodic dysmenorrhœa among sterile women, about two out of five cases, leads to a belief that this condition has some influence upon sterility. Gonorrhœa is an important factor. The reflux of semen is not so important a cause as supposed; the mucous discharge of the glands of Cowper and Duvernay are often mistaken for semen. A Chicago professor has found in that city that the hair on the mons veneris of sterile women is straight. He does not advise curling the hair as a cure for sterility, however. Sexual incompatibility is well known to exist. Sterility may be occasioned, when necessary, by obliterating the ends of the Fallopian tubes with the thermo-cautery. Some authors claim that consanguineous marriages are sterile. Darwin finds these slightly more fertile than non-consanguineous. He thinks this a fact because such marriages take place where there are large groups of cousins, and fertility becomes hereditary.

The cure of sterility is one of the difficult tasks of gynecology. Our imperfect knowledge of the cause is the origin of our trouble when we come to treatment. Women addicted to alcohol have become pregnant upon becoming teetotallers. Obesity is treated by a rigid diet, the menses increase as the obesity decreases, and the patient frequently conceives. A hyperæsthetic condition of the vagina sometimes necessitates anæsthetization. The radical treatment of endometritis by curetting is frequently followed by conception. The author has had good results from a solution of perchloride of iron one part, glycerine three parts, painted in the cervical canal in chronic endometritis. Constitutional treatment is often effective. Outerbridge has devised a new instrument for the cure of sterility. It consists of a steel wire, gold or silver plated, with a slight eversion at one end, with the other bent at right angles. This is inserted into the cervix. Catheterization of the Fallopian tubes is sometimes effective. Sea-bathing, residence at watering-places, and the use of mineral waters have a very beneficial effect on many stubborn cases. The crystalline phosphide of zinc, one-eighth grain, morning and evening, is highly recommended. Tea-drinking and the ingestion of tannin and sulphur are to be avoided. Belladonna has the reputation of promoting conception. According to Cohnstein, there are times with every woman which might be called the period of predilection for fecundation. If reflux of semen be the trouble, the hips should be elevated during coition, and the penis allowed to remain as long as possible in the vagina. The taking of the knee-chest position immediately after coitus is recommended, and perineorrhaphy is sometimes necessary. As a last resort, artificial impregnation is necessary in otherwise hopeless cases. It is disagreeable to all concerned, but there are no real moral reasons against it. An alkaline vaginal injection of phosphate of soda should precede the operation, to neutralize the vaginal secretions. Sexual intercourse should take place promptly; the syringe, new, free from infecting matter, should be at the exact bodily temperature, the semen taken up carefully, the nozzle inserted clear to the fundus, and the fluid injected.

An extensive bibliography accompanied this paper.

Dr. George W. Ryan, of Cincinnati, read a paper entitled

THE ORTHOPEDICS OF INFANTILE PARALYSIS.

The author reached the following conclusions:

1. That orthopedic treatment, in conjunction with local treatment of muscles, is useful in all children who have arrived at the walking age. It gives support and prevents deformity.
2. That it tends to preserve, in a measure, the proper balance between antagonistic groups of muscles by aiding the weakened group and restraining the normal ones.
3. That by this means the paralytic group are given the benefit of any movement of which they are capable, and in this way can they get exercise.
4. That it certainly can correct deformity.
5. That a heavy appliance, or one adjusted by lacing bands to the leg or thigh, does more harm than good.
6. That such measures are a necessity in the after-treatment of divided tendons and muscles.
7. That in most contractions it is better to divide than to stretch them.

Dr. C. S. Bond, of Richmond, Ind., read a paper entitled

EARLY DIAGNOSIS OF CHRONIC KIDNEY LESIONS.

This paper was really the report of a committee of one appointed at St. Louis last year. In conclusion he gave the following summary:

Albumin in the urine probably always means disease somewhere in the body. In so-called physiological quantities it may be referred to disease removed from the kidneys, and the cause as transient. In pathological quantities it signifies either inflammation external to the kidneys, or a lesion of these organs. Many patients with evident kidney lesions do not pass albumin. Albumin is inconstant, and bears no relation to the extent of the lesion; but when present must be respected as a prominent factor in diagnosis. It generally makes its appearance a long time after other well-marked symptoms have existed, and the disease is grave when it exists in pathological quantities, and the symptom therefore should not be awaited.

Casts bear an intimate relation to albumin, but appear later. They are strong proof of renal inflammation, as they carry, usually, a part of its epithelium. Differentiation of the varieties of kidney lesions can often be made from this fact; but they, like albumin, are inconstant. Many patients do not pass them at all, and they always appear too late as a factor in early diagnosis.

The specific gravity of the urine is not to be relied upon, unless the mean specific gravity of many specimens is taken for known quantities of urine for twenty-four hours. This would mean a small amount of urea passed within the time, since it is the dominant salt eliminated; therefore why not test for urea at once?

Some outward manifestations of ill-health, perhaps continued for years, always precede the passing of albumin and casts. These symptoms are in common with well-marked kidney lesions, and are not due to other discoverable physical causes. Cases, often without a change in these symptoms for years, begin passing albumin and casts. It is fair, therefore, to assume that the symptoms referred to are the result of some common cause which precedes the pronounced kidney lesions. This common cause seems to be something which produces extension,

and often inflammation, of serous membranes, which at the same time, or remotely, involves the kidneys. What this cause is, we can at present only conjecture; but many of its pathological effects might be turned to advantage in early diagnosis. Urea is excreted in abnormally small quantities in cases of well-marked kidney lesions. It is also so excreted in cases having the prominent physical symptoms without albumin and casts. It is interchangeable as a means of diagnosis with the outward signs of the disease, *i.e.*, a knowledge of ill-health being also a knowledge of the amount of urea passed, and *vice versa*. Urea is excreted in small quantities for months, and often years, before albumin and casts appear, therefore a knowledge of this excretion is invaluable as a diagnostic sign of early lesion.

The diminished quantity of urea eliminated is the result of constitutional disturbances, which precede the local lesion for long intervals of time. Active treatment, which would be harmful in other diseases having some symptoms in common, will identify this, generally relieves, and frequently apparently cures.

TREATMENT OF THE INSANE IN RELATION TO SCIENCE

was the subject of a paper by DR. ORPHEUS EVARTS. Superintendent of the College Hill (Cincinnati) Sanitarium. This paper was very laudatory of the modern treatment, He did not believe insanity was a disease of civilization. It was a disordered brain. All who have brains are liable to this disease.

THE FORMATION OF AN ARTIFICIAL URINARY CANAL

was the subject treated by DR. W. N. WISHARD, of Indianapolis.

DR. WILLIAM C. WILE, of Danbury, Conn., in discussing this paper, described an operation for this object which was original with himself. The paper was further discussed by Dr. G. Frank Lydston, of Chicago.

PURULENT CONJUNCTIVITIS

was the subject of a paper by DR. D. A. THOMPSON, of Indianapolis. He insisted on cleanliness, washing the eye, if necessary, every half hour with a saturated solution of boracic acid in water. He also used the nitrate of silver, but had not met with success in the use of bichloride of mercury. Discussed by Dr. Knapp, of Evansville.

SYMPATHETIC DISEASES OF THE EYES FROM INFLAMMATION OF THE NASAL PASSAGES

was the title of a paper by DR. FRANCIS DOWLING, of Cincinnati. He thought the medical attendant was too prone to treat the eye disease and overlook the disease in the nose. He should recognize the fact that the origin of the disease is in the nose and not in the eye, and shape his treatment accordingly.

"The Cautery *v.* the Snare" was the subject treated by Dr. E. R. Thompson, of Indianapolis.

DR. FLETCHER INGALLS, of Chicago, Ill., read a paper on

CHRONIC TONSILLITIS.

He insisted on not subjecting children to the torture of removal of the tonsils without the benefit of an anæsthetic. The paper was discussed by Drs. William Porter, of St. Louis, and E. R. Lewis, of Indianapolis.

Dr. I. N. Bloom, of Louisville, reported two cases of "Amputation of the Penis," and discussed the subject.

DR. C. F. MCGAHAN, of Chattanooga, Tenn., read a paper on

THE TREATMENT OF PULMONARY PHTHISIS.

He thought when there were present symptoms of the disease without inflammation, the majority of the cases are capable of cure. He reviewed the treatment of phthisis since the discovery of Koch, and related his personal experience. He had phthisis in 1882 (but didn't look as if he had) and had recovered. In treatment, we have returned to nutrition and pure air. We should always let the patient have a thread of hope, though it may be a false one. The care of the stomach was the great thing. Give as few medicines as possible, so as to keep the stomach in good order. The hygienic treatment should take precedence over the medical. As for health-resorts, he favored Asheville and Aiken.

"Differential Respiration" was the subject of a paper by Dr. F. C. Wilson, of Louisville, who showed his bellows for this purpose.

CONTAGIOUSNESS OF PHTHISIS.

The report of the committee appointed last year was made by Dr. William Porter, of St. Louis, Mo. He thought the word portageous was more accurate than contagious. He thinks the evidences of transmissibility in tuberculosis are conclusive. Two hundred and fifty-one English physicians, in active practice in families, have replied in favor of the theory of the transmissibility of tuberculosis. The New York Board of Health has passed resolutions which acknowledge this contagion. The fact has been published that there have been no cases of tuberculosis among the nurses and house physicians at Brompton Hospital. This is true, on account of the excellent hygiene of that institution, and does not prove the non-contagiousness of the disease. It has been written that there was no tuberculosis among the North American Indians, and but little among the early settlers of New England. One hundred years ago the climate of New York was thought to be good for tuberculosis by Europeans, who sent their patients there; then, later, the prairies of Illinois were lauded for the same purpose; later still, the mountains of Colorado and the valleys of California. He emphasized the fact that the care of localities used as resorts for consumptives was very important, so that they do not get infected with the disease. He recommended that consumptive patients use cuspidors in which there was a 1 to 1,000 solution of bichloride, as it has been demonstrated that a weaker solution has not always the potency sufficient to destroy the bacilli. He recommended, as a prophylactic measure to the spread of tuberculosis, the most careful inspection of meat and milk. He considered the future of this subject a bright one.

DR. EDWIN RICKETTS, of Cincinnati, read a paper on

TUBERCULAR PERITONITIS, WITH REPORT OF A CASE,

in which he advocated the operative treatment in this trouble.

DR. THEODORE POTTER, of Indianapolis, said that no one doubted that the tubercular bacillus causes the disease. We cannot doubt this any more than we doubt the laws of gravitation. We must remember that tuberculosis is a local disease just as much as is an abscess. It may become general, but it is not so in the beginning, and only accidentally becomes so. Tuberculosis is not generally hereditary. We are now on more positive and definite ground in regard to this disease than ever before.

The paper was further discussed by Drs. Earley, of Pennsylvania; Cutter, of New York; Brayton, of Indianapolis; Chapman, of Toledo; Meyers, of Fort Wayne; Reynolds, of Louisville; McGahan, of Chattanooga; Ricketts, of Cincinnati; Porter, of St. Louis.

DR. BRANSFORD LEWIS, of St. Louis, read a paper on

THF PRINCIPLES THAT SHOULD GUIDE US IN THE TREATMENT OF GONORRHŒA.

The question of bacteriology is considered of the first importance in every subject of medical or surgical science; the admission of this leads to an inquiry as to what the study and acquaintance with the life-history of the gonococcus has done for our assistance in the treatment of gonorrhœa. He concluded that our knowledge had only served to mollify the severity to a certain extent, and somewhat shorten the duration of the disease. Beautiful and touching theories had been constructed to explain how the gonococcus would quail with fear at the prospect of being literally boiled alive by a hot injection, or

of being washed out into the cold world by a prolonged irrigation, or dried into an Egyptian mummy of a coccus in the arid soil of an astringent, antiseptic, magic-healing, absorbent powder, etc. But experience with these various agents has shown that none are infallible; that all are subject to the varying influences met with in treating after the older prevalent methods.

It must be admitted that germicides and antiseptics do kill gonococci—in culture-fluids; why not then in the urethra? For this reason: The gonococci, in preparing for the conflict, do not foolishly remain where they may be brought under the influence of medicaments; they make their landing and start immediately for the woods, so to speak. They penetrate between the epithelial cells and reach the basement (connective tissue) layer, which obstructs their farther progress. Thus medicines are prevented from reaching them by the tissues themselves.

He concluded that the proper treatment of gonorrhœa should be based on the idea, not of checking it in the early but established stages, but of carrying it through its various stages, with allowing as little suffering from annoyance and pain, etc., as possible; limiting it as much as present powers will permit, and preventing complications and sequelæ.

In the second stage lanolin, medicated with non-irritating antiseptics, and in the subacute, or third stage, the addition of some mildly stimulating astringent is excellent treatment. The application was made with an instrument, which was shown, an instrument-box having a catheter stem; a late modification was a soft vulcanized rubber stem. Resorcin was recommended as a medicinal agent; boric acid or thalline is probably best in general. Bichloride of mercury and carbolic acid are too irritating.

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 13 to October 19, 1889.*

HAVARD, VALERY, Captain and Assistant Surgeon. Leave of absence extended one month. Par. 3, S. O. 240, A. G. O., October 15, 1889.

BRECHEMIN, LOUIS, Captain and Assistant Surgeon. Granted leave of absence for one month. Par. 1, S. O. 98, Headquarters Department of the Platte, October 12, 1889.

HEGER, ANTHONY, Lieutenant-Colonel and Surgeon. Relieved from duty in Division of the Atlantic, and ordered for duty as Attending Surgeon, Washington, D. C. Par. 2, S. O. 241, A. G. O., October 16, 1889.

ADAIR, GEORGE W., Captain and Assistant Surgeon. Leave of absence extended for fifteen days. Par. 15, S. O. 238, A. G. O., October 12, 1889.

O'REILLY, ROBERT M., Major and Surgeon. Granted leave of absence for six months, with permission to leave the United States. Par. 3, S. O. 241, A. G. O., October 16, 1889.

LORING, L. Y., Major and Surgeon. Sick leave extended two months on Surgeon's Certificate of Disability. Par. 16, S. O. 241, A. G. O., October 16, 1889.

BRADLEY, ALFRED E., First Lieutenant and Assistant Surgeon. Relieved from duty at David's Island, N. Y. H., and ordered to Fort Omaha, Neb. Par. 2, S. O. 241, A. G. O., October 16, 1889.

EVERTS, EDWARD, Captain and Assistant Surgeon. Relieved from duty at Fort Apache, Ariz., and ordered to David's Island, N. Y. H. Par. 2, S. O. 241, A. G. O., October 16, 1889.

MAUS, LOUIS M., Assistant Surgeon. Relieved from duty at Fort Porter, N. Y., and ordered to Fort Stanton, N. M. Par. 10, S. O. 242, A. G. O., October 17, 1889.

BRECHEMIN, LOUIS, Captain and Assistant Surgeon. Relieved from duty at Fort Laramie, Wyo. Terr., and ordered to Fort Apache, Ariz. Terr. Par. 2, S. O. 241, A. G. O., October 16, 1889.

HARRIS, H. S. T., First Lieutenant and Assistant Surgeon. Relieved from duty at San Antonio, Tex., and ordered to Fort Keogh, Mon. Par. 2, S. O. 241, A. G. O., October 16, 1889.

GIBSON, JOSEPH R., Surgeon. Relieved from duty at Fort Sheridan, Ill., and ordered to Governor's Island, N. Y. H. Par. 10, S. O. 242, A. G. O., October 17, 1889.

GARDNER, EDWIN F., Assistant Surgeon. Relieved from duty at Fort Lewis, Col., and ordered to Fort Porter, N. Y. Par. 10, S. O. 242, A. G. O., October 17, 1889.

EWEN, CLARENCE, Surgeon. Relieved from duty at Madison Barracks, N. Y., and ordered to Willets Point, N. Y. Par. 10, S. O. 242, A. G. O., October 17, 1889.

GIRARD, ALFRED C., Surgeon. Relieved from duty at Boise Barracks, Idaho, and ordered to Fort Niagara, N. Y. Par. 10, S. O. 242, A. G. O., October 17, 1889.

HALL, JOHN D., Assistant Surgeon. Relieved from duty at Fort Niagara, N. Y., and ordered to Madison Barracks, N. Y. Par. 10, S. O. 242, A. G. O., October 17, 1889.

TAYLOR, MARCUS E., Assistant Surgeon. Relieved from duty at Fort Stanton, N. M., and ordered to Boise Barracks, Idaho, Par. 10, S. O. 242, A. G. O., October 17, 1889.

*Official List of Changes in the Medical Corps of the United States Navy for the week ending October 19, 1889.*

BERTOLETTE, D. W., Surgeon. Detached from the Franklin, and ordered to duty at Naval Hospital, Philadelphia.

RUSH, N. H., Passed Assistant Surgeon. Detached from Naval Hospital, Philadelphia, and ordered to the Saratoga.

HIBBETT, C. T., Passed Assistant Surgeon. Ordered to the Franklin.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 19, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 55 | 12 |
| Scarlet fever | 32 | 3 |
| Cerebro-spinal meningitis | 1 | 3 |
| Measles | 28 | 1 |
| Diphtheria | 69 | 24 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

URINE OF BUSINESS MEN.—There is no question that too little attention is paid to urinalysis by the majority of practising physicians, especially the microscopic part of the work. All know how to test for albumin and sugar, but very few can make a quantitative analysis of urea, and a still smaller number have no microscope, neither do they know the most common crystals. An examination of the urine will reveal the incipiency of many diseases which can be throttled at the outset, and then the physician can exercise his prophylactic powers, the most useful part of his life work, for it is better to prevent than to cure. Dr. Clifford Mitchell, of Chicago, in the *Medical Era*, seems to have been especially interested in the urine

of business men, and he emphasizes some important points. The urine of the over-worked and over-fed American business man usually shows in the beginning, before any renal disease is actually present, the following characteristics: The total quantity of the urine for the twenty-four hours is greatly reduced, sometimes to half the normal quantity. The color is usually, therefore, darker than normal, and there is an abundant sediment in which urates, uric acid, and often calcium oxalate may be seen with the microscope. The urine being diminished in quantity, and the acidity relatively increased, the urates and uric acid cannot be held in solution as they ought to be. Estimation of the total quantity of urea will almost invariably show this substance to be diminished to a figure considerably below normal. Perceptible traces of albumin and sugar I occasionally find in the urine of hyperactive business men, but in many cases both these constituents are as yet absent. I say "as yet," for sometimes, if all warnings are unheeded, one or the other of these unwelcome visitors, in time, may make its appearance. I regard persistent decrease in both fluids and solids of the urine of great significance in those who eat hearty and exercise little. It is not necessary that either albumin or sugar be present—there is enough trouble without them. When a man of average weight voids daily no more urea than we find in the urine of a delicate woman, or a bedridden patient, it is time to cry "Halt." I have found these patients with diminished urea and crystalline sediments have all sorts of aches and pains. Headache is a very common concomitant. Sleeplessness is another. If I could have my own way I would estimate the urea in the urine of every patient in the country suffering from insomnia, or restless unrefreshing sleep. Not all insomnia is due to lithæmia, but many cases, apparently hopeless, could be helped were the conditions properly understood.—*Saint Joseph Medical Record.*

Tests for Minute Amounts of Albumin.—The importance of a trustworthy and convenient test for minute proportions of albumin in urine is coming to be more and more widely recognized. The subject is treated of exhaustively and very clearly in a work recently issued in Paris, entitled "Traité de l'Albuminurie et du Mal de Bright," by Dr. E. Lecorché, an adjunct professor of the Faculté de Médecine, and Dr. C. Talamon, a physician to the hospitals. These authors have devoted much care to a comparison of the principal compound reagents used for the detection of minute amounts of albumin. Those that they have experimented with more particularly are: A mixture of acetic acid and potassium ferrocyanide; a mixture of acetic acid and mercury bichloride; a mixture of acetic acid and potassium and mercury iodide (Tanret's); a mixture of acetic acid, carbolic acid, and potash (Millard's); a saturated solution of sodium chloride acidulated with hydrochloric acid (Roberts'); and a mixture of sodium phosphotungstate and citric acid (Oliver's). Tanret's test has commonly been considered equal, if not superior, to all other tests for small quantities of albumin, but Lecorché and Talamon give Millard's the preference. So far as the application of the various tests without the aid of heat is concerned, they say: "We have no hesitation in giving the preference incontestably to the American author." Both Tanret's and Millard's tests, they remark, show albumin in the proportion of 1 part to 200,000 and even 300,000 parts; but, while the disk produced with Tanret's is pale and diffuse, that caused by Millard's is much more distinct, although very thin. Millard's test, they repeat, is the surest and most convenient. Besides the greater distinctness of the albuminous ring produced by it, the substances that may lead to error in drawing deductions from its use are only urates, peptones, and mucin, and they are easily recognized. Urates and peptones are precipitated on gently heating the test-tube at the level of contact, and mucin, which always causes a dusty turbidity *above* the line of contact, is readily distinguished with a little practice. The authors add that, when heat is employed, Oliver's test shows some advantages over both Tanret's and Millard's. It is satisfactory to have such definite and authoritative statements of the merits of a particular test, and it is gratifying that the preference is so distinctly accorded to a test devised by one of our own countrymen. It may be well to remind our readers of some facts connected with his test for albumin. The solution is composed of two parts, by weight, of ninety-five per cent. carbolic acid, seven of glacial acetic acid, and twenty two of liquor potassæ. When the quantity of albumin to be tested for is very minute, the urine should be clarified and allowed to trickle down slowly upon the solution.—*The New York Medical Journal.*

Heredity.—Sir William Turner, Professor of Anatomy in the University of Edinburgh, delivered an address on "Heredity," in which, while pointing out that in some cases structural lesions, such as hare-lip, color-blindness, and deaf-mutism, are transmitted, he also maintained, in opposition to some physiologists, that acquired characters can be transmitted from parent to offspring. He said, in concluding his address, that whatever the origin of man's frame, whether by evolution or otherwise, it could scarcely be expected ever to attain greater perfection than at present. Man was, however, also endowed with a spiritual nature, and the kind of evolution to be hoped and striven for was the perfecting of this spiritual nature, so that the standard of the whole human race might be elevated and brought into more harmonious relation with that which was holy and divine.

An American View of Medicine in Germany.—In the course of an address on the "Remedy for Overcrowding in the Medical Profession," Dr. Boyd Cornick (*The Journal of the American Medical Association*, May 4, 1889) makes the following statements. "Germany is probably excelled by no other government in the world in the stringency of its laws regulating admission to the ranks of the medical profession. Not only is the preliminary course of study long and arduous; not only must each aspirant have passed through every successive grade of prescribed preparatory instruction; not only must he have secured the endorsement of some noble university, justly famed for the high standard of learning which its degrees imply; not alone must the aspiring youth devote many years of time and many hundreds of thalers to a completion of the course marked out for him by the authority of the State; but, in addition to all this, even though the possessor of a university degree, he must finally pass a rigid and awe-inspiring Staats-examen before a government licensing board; and then, if successful in this latest ordeal, he is permitted to practise medicine within the confines of the German Empire. As a consequence of all these stringent requirements, the medical profession of Germany leads the vanguard in the world-wide march of progress in the medical sciences. Such results certainly justify the high standard of qualification requisite for entrance into the medical profession of Germany. But, alas! even in that favored land, whose laws regulating the practice of medicine are exceeded in stringency by those of probably no other government under the sun, we are confronted with the same problem of an overcrowded medical profession, which is harassing the minds of medical men throughout the confines of our civilization."

Wordly Wisdom.—Professor Charpentier, of Paris, gives the following advice to physicians, as to the most prudent answer to be given when asked what they think the sex of the child is going to be. "Reply by asking the mother what she would prefer in the child, and then give it as your opinion the opposite is the one to be looked for. In this way, if the sex turns out to be the one you have prognosticated, you will be thought a wonderful man, while if it proves to be the one the mother has wished for, she will be so pleased that she will easily overlook your error."

### ELECTRICAL INJURIES.[1]

BY CHARLES L. DANA, A.M., M.D.,

NEW YORK

WITH the development of new industries or inventions there occur new disorders or new factors in the production of disease and of injuries. These are always slight in comparison with the benefits that come from great and successful industries, yet they must be taken into account by the physician and surgeon.

We are now entering upon an era of tremendous activity in the practical application of electricity. Aside from the telegraph and telephone, electricity is becoming rapidly introduced as a method of lighting, heating, motor power, and locomotion. There were in this country alone in March, 1889, over 219,000 arc-lights, 2,500,000 incandescent lights, and over 5,000 electrical plants, with $69,000,000 of capital invested (Duncan, *Electrical Review*, March 2, 1889). There were 53 electrical railways, operating 329 cars. These figures are increasing with the greatest rapidity.

Along with the introduction of these new industrial methods we are meeting accidents and injuries of all grades of severity; and in time there will be associated with electrical systems, classes of injuries some of which will be perhaps peculiar to them, some will resemble those known as railway brain and railway spine, traumatic hysteria, and other neuroses or psychoses, while a large number will be only of the ordinary surgical character.

The means by which the electrical current does harm varies, naturally, with the form in which it is used. The telegraph and telephone produce peculiar neuroses, due not to the electrical current, but to the peculiar demand made upon the nervous system of the operator, the results being telegraphers' cramp, aural and mental disorders of telephone transmitters, etc. Electricity only does direct injury to telegraph operators through lightning, or connection with wires carrying strong currents. Of injuries directly connected with electro-motors and electric railways there is little yet known. In electric roads run by a bare wire overhead, accidents are possible, though the current is not so strong as that usually employed for arc-lights, being about 500 volts. Most of the observed cases of electrical injury come from the apparatus carrying electrical currents for lighting and power.

The currents most in use are interrupted and alternating currents of 1,000 to 2,000 volts electro-motor force. Such currents, when received by the human system, have varying effects, in accordance with the mode of contact and the susceptibility of the individual. In some cases they merely stun the victim, and burn the parts in contact with the wire. In others, they have been known to produce permanent paralytic effects. Of such cases, however, there are only two on record. In still other instances almost instantaneous death results; while, sometimes, a mental shock is produced, which affects the system just as other shocks do, causing conditions known as traumatic hysteria or neurasthenia.

The number of fatal accidents from electrical currents during the past ten years has been variously estimated at from 100 to 200. In this city, according to a report kindly furnished me by the Board of Health, it has been: 1886, 0; 1887, 3; 1888, 5; up to October 19, 1889, 5. There can be no doubt that an alternating electrical current of 1,200 volts, properly applied, will surely kill a human being. I do not wish to bring up the question of death by this means, however, but only to state that the physiological fact is, I believe, an indisputable one.

A further physiological fact, that has been in my opinion established, is that the electrical resistance of the human body averages less than 2,500 ohms, with strong currents. The observations regarding resistance made by Mr. Kenelly under the direction of Mr. Edison were, as I have good reason to believe, carefully and scientifically performed, and constitute a contribution of indisputable value to this subject. We know that human resistance varies considerably with the individual, these variations depending chiefly upon the moistness, thickness, and vascularity of the skin, and upon the carefulness of the contact; also, that it decreases rapidly with the continued passage of the current, and is less with very strong currents than with weak ones. Experience seems to show also that the maximum alternating current which it is safe to come in contact with is one not over 400 ohms, though I do not believe that even this could kill, except it were applied directly to the brain. There is still a dispute as to whether the continuous, interrupted, or alternating current is the safer, and into this controversy I do not propose to enter. A current of either kind stronger than 600 ohms would not be a pleasant thing to take.

The electrical current burns or not according to the dryness of the skin and clothes, and the consequent degree of resistance. With a dry skin there is more burning, less penetration, less shock, and less danger of death. With a wet skin and good connections, there is little burning and more serious internal effect. Dr. Biggs has noted that most of the fatal electrical accidents have occurred on or after rainy days.

The accidents and injuries from electrical currents have so far shown that they kill, or they burn severely, or they do no permanent harm. This, at least, is the rule.

When a person by accident receives a current of from 300 to 1,000 ohms, it promptly knocks the recipient down, and may cause a temporary tetanus even if the current is at once broken. Consciousness is not usually lost, but severe, agonizing pain and terror are felt. In a few moments the muscles relax, the patient is able to move, he gradually picks himself up, and in a short time is in fair condition. His arm or leg, or whatever part was in contact with the wire, feels numb for some hours or even longer, but I know of no certain cases of local paralysis.

A vivid account of the effects of a strong but non-fatal continuous current is given in the *Occidental Medical Times*, 1889, p. 562. The victim, an electrical engineer, took hold of a wire in each hand and made the connection through his body. The current as subsequently measured was over 1,400 volts, and the current strength must have been about 1 ampère. He described his feelings as follows:

"'My hands were paralyzed, my arms were as stiff as bars of iron, and the cords stood out in large bunches; my head was turned round in the direction of the current; my eyes bulged out with burning pressure and glazed over; then I lost my senses and fell to the floor.' The fall pulled one of the wires, which was attached to the ceiling, out of his hand and so broke the circuit. He at once recovered his senses, and attempted to recouple the

[1] Read at a meeting of the Practitioners' Society, October 4, 1889.

wires, when some of the employees interfered, but he was sufficiently collected to give the necessary directions for opening the circuit. The time of contact was not less than five nor more than eight seconds. There was no pain to speak of—not more than would be felt from a strong galvanic battery. His hands and fingers were burnt, but owing to the fact that they were moist, and that he had a firm hold on the wires, the burns were slight. The shock to the nervous system was very severe, and two months later the effects were still evident."

The electricity, even in fatal doses, does not usually much affect the nervous structure, but tends rather to cause carbonization of the blood, paralysis, and distention of vessels, and sometimes hemorrhages, with occasionally disruption of muscular and vascular or other tissue. A direct disorganizing effect upon nerve-centres seems possible, however, from two cases of organic paralysis of which accounts are given.

A good many electric-light employees get minor shocks which stun them a little, but they do not seem to mind it. In some of our dispensaries there is, I am told, quite a contingent of cases of burns and stunning, with numbness; but it is only the burns that are complained of.

In more sensitive persons it is quite possible, however, that morbid psychical and neuro-psychical conditions may be produced.

Dr. William G. Thompson recently reported a curious case of traumatic hysteria. The details will be published in full. I saw and examined the patient, however, and Dr. Thompson kindly consents to my referring to it. A man, aged fifty, not long ago saw an Italian killed by an electric wire. Two weeks later, while walking along the street, an electric wire which had just been cut fell and struck his head. He grasped it in his hand, and fell down. He says that he knew nothing until a few hours later, when he found himself in the hospital. He then had right hemiplegia and hemianæsthesia, including the senses of smell and taste. There was limitation of the visual and auditory fields, bone deafness, pharyngeal anæsthesia, and all the stigmata of typical hysteria. The wire which struck him was a "dead" one; and the blow was slight, and caused no contusion.

A case illustrating the fact that the strongest currents may be taken without local or general paralysis is the following, which I shall give only in outline:

A young man, aged twenty-three, was accidentally struck by a live wire. He grasped it with his left hand, and instantly fell down. The current, which was that of the arc-light, passed through the arm and body for several moments. He remembers only feeling a sudden blow on the head which knocked him down and made him partially unconscious. He heard voices about him, saw a glimmering light, felt intense pain, and momentarily expected death; finally he lost consciousness.

The result of the injury was that his left hand was so severely burned that it finally had to be amputated, but the arm was not in the least paralyzed or anæsthetic, and the effect on the general bodily functions was *nil*. It is a curious fact, indeed, that some patients feel better after severe electrical shocks. In others, as already intimated, the condition known as traumatic neurasthenia or hysteria may supervene. Dr. Peterson has had under observation a case of this kind. I have also met one such case.

A severe and sometimes fatal accident occasionally befalls the linemen. While at work on the poles they receive a shock which stuns them so that they fall to the ground and receive their real injury from this fall.

Such an accident came under my observation recently, the case being taken to the Gouverneur Hospital in the service of Dr. Ward. The man was knocked off the telegraph pole by an electrical shock, and fell, fracturing the base of his skull. He eventually recovered.

My present article is intended to be brief and introductory, and I shall not attempt to cite further cases. It has not been my purpose especially to call attention to the dangers of electrical currents or to exaggerate their importance. The fact is that the practical introduction of electricity has been attended with much less fatality than that caused by gas, steam, railroads, and many other of the inventions of modern life.[1]

*Summary.*—Some of the points which I have wished to make in the present article may be summarized here:

The extraordinary increase now going on in the practical application of electricity—there being already nearly $100,000,000 invested in lights and power alone.

A practically new class of injuries met in connection with the new industries. Such injuries have been heretofore produced only by lightning, and they have been consequently rare.

These injuries are not numerous or serious as compared with those met with in connection with other great industries. There have been in ten years only about 100 deaths in the whole world from artificial electrical currents. The railroad kills annually over 2,500 people (2,541 in 1880) and injures about 6,000 in the United States alone.

Electrical currents produce three kinds of severe accidents:

They kill at once; or they burn severely; or by the mental and physical shock they cause traumatic neurosis.

Usually, if they burn severely they do not kill. Hence, practically, the rule is, if contact with electrical wires does not kill, the victim gets only a burn or a harmless shock.

In very rare cases the current seems to affect the nerves or nerve-centres, causing paralysis.

The minimum current safe to receive is not definitely known. Probably eight hundred to one thousand volts of continuous current, and a third less of alternating current, would not be fatal.

The wires for lighting and for power carry the more dangerous currents.

---

## A SUCCESSFUL CASE OF LAPAROTOMY AND SUPRAVAGINAL AMPUTATION OF THE UTERUS FOR RUPTURE.[2]

By HENRY C. COE, M.D., M.R.C.S.,

PROFESSOR OF GYNECOLOGY AT THE NEW YORK POLYCLINIC; SURGEON TO THE NEW YORK CANCER AND MATERNITY HOSPITALS; ASSISTANT SURGEON TO THE WOMAN'S HOSPITAL.

On September 8th, at 1 P.M., I was called by Dr. R. H. Hayes to perform Cæsarean section in a desperate case of labor. Not knowing what I would find, I hastily collected a few instruments, and with my associate, Dr. G. A. Kletzsch, accompanied the doctor to a tenement-house a mile distant, in the fourth story of which we found the patient attended by Dr. W. A. Hawes, who had been called to see her in consultation. She was a healthy Irishwoman, twenty-three years of age, with a rapid, feeble pulse, evidently in a state of collapse. The gentlemen in attendance feared that rupture of the uterus had taken place two hours before. Examination of the abdomen revealed two tumors, a larger one filling the right side of the abdomen and extending as high as the ensiform cartilage, and a smaller occupying the left iliac fossa, both being firm and unyielding. It was evident that the former was the body of the uterus, tilted over to the right and in a state of tetanic contraction, and the latter the head of the child. Palpation of the abdomen above the latter gave an ominous gurgling sound, suggestive of free fluid in the peritoneal cavity. I learned that prolonged attempts had been made to extract the child by forceps and version. Introducing my hand into the

[1] For example, in France, among 223,000 railway employees there is an annual average of 239.5 killed and 1,850.4 wounded. In Germany there are 1.35 per 1,000 of railway servants killed and 3.09 per 1,000 wounded. In England the annual mortality is 2.43 per cent. In the United States among 418,957 employees, in 1880, there were 923 killed and 3,617 injured—a higher rate than anywhere in Europe (U. S. Census). In coal mining the ratio in France is 1.56 per 1,000 of killed, 8.87 per 1,000 of wounded.—*Proceedings of Congress on Accidents to Workmen*, Paris, 1889.

[2] Read before the Section on Obstetrics, New York Academy of Medicine, October 24, 1889.

vagina, I discovered that the anterior lip of the cervix was deeply lacerated antero-posteriorly, while another laceration extended through the vaginal junction on the left side. Passing my finger through the rent, I entered the abdominal cavity.

The child, which was of unusually large size (fifteen pounds), and was dead, presented in the left dorso-anterior position, with the right hand and foot prolapsed, and was firmly impacted; the head seemed to be partly outside of the uterus. Believing that a further attempt at version would only extend the tear, I at once decided that laparotomy offered the only prospect of saving the woman, and proposed this to the husband, who consented. The patient's condition was desperate, and the surroundings were such that any approach to antisepsis seemed to be impossible, but I felt that she ought to have the chance. She had lost a large amount of blood and her pulse was so feeble that hypodermics of brandy and ether were given. Fifteen minutes after my arrival, assisted by the gentlemen mentioned, and by Dr. Huntington, who had been sent for, I made a free incision, eight inches in length, through a very fat abdominal wall and opened the peritoneal cavity, which contained a quantity of fluid blood and clots. A rent was found extending upward from the cervix through the left broad ligament and the lower uterine segment. The head of the child lay in the left iliac fossa outside of the uterus, being grasped by the edges of the tear. I saw at once that this was not a case for suture of the uterus, as arterial hemorrhage was going on from the vessels of the lacerated broad ligament, and the condition of the patient was such that no time was to be lost. The uterus was turned out of the cavity, the cervix constricted by a piece of rubber tubing cut from a fountain-syringe (I had forgotten my écraseur in my haste), and the child was extracted through the rent. Without waiting to remove the placenta, I secured the tubing with a pair of artery-forceps, excised the uterus with the ovaries and tubes, and proceeded to tie the bleeding vessels. This part of the operation was completed in twelve minutes. The utero-sacral ligament on the right side was also badly lacerated. The vessels having been secured, and the torn peritoneum sewn with a continuous catgut suture, the peritoneal cavity was thoroughly irrigated with hot water, and the stump was trimmed down and secured in the wound with knitting-needles. No drainage-tube was used.

The bladder was carefully inspected, and was apparently uninjured. The cervix had been so badly torn that I expected it to slough out, as subsequently happened. The wound was hastily closed and the patient was placed in bed in fair condition in less than an hour after the operation, the delay having been due to the time spent in suturing the torn peritoneum. She rallied well, but had a pulse of 140 to 150, and no hopes were entertained of her recovery. From the outset she was free from nausea, and was able to take stimulants. On the second day her temperature rose to 102°–103° F., and there was general abdominal tenderness and distention, but, by maintaining free catharsis and using the ice-bag, peritonitis was aborted. The urine was drawn during the first four or five days, after which it was usually passed spontaneously. The stump quickly necrosed; on the fourth day I replaced the tubing by a Koeberlé's *serre-nœud*, and removed the entire mass at the end of a week, packing the cavity with iodoform gauze. The patient's condition at this time was not entirely satisfactory. She took nourishment and stimulants freely, but her pulse remained at 120 and her temperature rose every evening to 101°–102° F. At one time an exhausting diarrhœa threatened her life. She complained of no pain, but I feared suppuration of the hæmatocele which had formed in the left broad ligament. As there was considerable discharge from the vagina, injections of creolin (1 to 400) were given after the first few days, with iodoform suppositories.

Early in the second week the urine began to escape per vaginam, although the patient could retain it to some extent. A careful examination with the finger and speculum showed that a cervico-vesico-vaginal fistula had been established, and that there was considerable sloughing of the upper portion of the vagina. All the necrosed tissue at the bottom of the abdominal wound was picked away, until nothing remained of the cervix but the portio vaginalis; the wound granulated nicely, but there was a free communication with the vagina through which urine and the douche-water sometimes welled up. After the second week the patient's temperature became normal, with an occasional evening elevation to 100°–101° F., and she complained of nothing but the constant dribbling of urine. Her subsequent history was uneventful. She was allowed to get up at the end of the fourth week, at which time the wound still communicated with the vagina, and not quite so much urine dribbled away as at first. At the end of the fifth week the abdominal wound had entirely closed.

It is hardly necessary to add that the after-treatment of such a serious case in a dirty tenement-house required the constant personal supervision of a physician, and I take pleasure in acknowledging my indebtedness to Dr. Kletzsch, and especially to the attending physician, Dr. Hayes, for their assistance in this most thankless task. Without the exercise of constant vigilance the patient would certainly have succumbed to the operation or to the subsequent complications.

Before commenting on this case, it is important to classify it. As my friend Dr. Robert Harris, of Philadelphia, has clearly pointed out, it is neither a Porro nor a Cæsarean section proper, but is an operation *sui generis*. I was myself misled by a paper of Professor Lusk's in which he refers to the two successful cases of "Porro's operation" for rupture of the uterus, reported by Slavjansky and Fontana. If it receives any name at all, it should be called "Prevôt's operation," since Prevôt, of Moscow, reported the first case (unsuccessful) in which the ruptured uterus was amputated after removal of the child through the rent, without previously incising the organ. The entire difference between this procedure and the Porro-Cæsarean operation lies in the fact that in the former hysterotomy is not performed. Through the courtesy of Dr. Harris, who has taken the greatest interest in my case, I am enabled to present a table prepared by him, which, so far as I have been able to determine by personal research, with the addition of two other cases, is complete up to date.

I at first supposed that mine was the only case in the United States, as I believe that it is the only successful one, but Dr. M. Price has kindly sent me the notes of a similar operation performed last April, which I will quote in order to emphasize the difference in treatment in the two instances. Dr. Harris informs me that there have been ten true Porro-Cæsarean sections for rupture of the uterus in this country, four women having been saved. The details of Dr. Price's case are briefly as follows: He was summoned by a midwife to see a woman who was in labor with her seventh child, and had lost so much blood that she was pulseless. On examination the child was found to be presenting transversely, the left foot and leg extending into the peritoneal cavity through a rent in the uterus. The doctor delivered the child after performing version, and sent for assistance. The abdomen was opened, the placenta was removed from the abdominal cavity, and the uterus was lifted out. The organ had "not only a long laceration in its left wall, but was considerably torn from its vaginal attachment, with no apparent contractile power left." The *serre-nœud* was applied, and the uterus was removed. The patient succumbed half an hour later.

The reporter explains that his reason for delaying the operation was the want of counsel and assistance, and the fact that he could not communicate with the husband until an interpreter had been summoned. While appreciating the doctor's position, which was more difficult than my own, since I was able to operate without delay, I cannot help thinking that if he had waited for assistance *without performing version*, and then had operated

| 14 | | Dr. Kehrer | Heidelberg | Hospital | | | | | Recovered | Dead | | Extra-peritoneal | | Ibid. |

[1] In this case the accident occurred in the ninth month of pregnancy, the patient being knocked down by a street car. She was brought to the hospital in collapse. The case was in other respects parallel with the one reported.

[2] The patient was shown at the German Gynecological Society last June, at which time Kehrer's case was reported.

as rapidly as he did (fifteen minutes) the result would have been different. My case was even more unfavorable than his, since the patient had been under an anæsthetic for three hours, during which time the soft parts suffered severe injury from hands and instruments. There was greater laceration of the uterus and surrounding tissues, and, moreover, more than two hours elapsed between the rupture and the operation. I am sure that a further attempt at version on my part would have terminated the case fatally in a few minutes. Since the child was dead in all the cases reported, there seems to be no reason why we should destroy the small chance which the mother has of being saved by laparotomy, by trying to perform version with the certain risk of increasing the tear in the uterus, and adding to the existing shock—that is, if we intend to perform laparotomy at all. If no operation is contemplated, the case is different, and does not belong to the present category.

In conclusion, I would say that, given the same conditions, I would adopt precisely the same method of procedure in another case of rupture of the uterus, because I believe that it would offer the best chance of saving the patient, for the following reasons:

1. The operation can be performed in the shortest possible time. Time is the most important element in these desperate cases.

2. It is impossible to properly suture such an extensive rent, with contused edges, as the one described, which begins at the cervix and extends through the broad ligament up into the body of the uterus. There is imminent risk of hemorrhage after removal of the temporary constriction.

3. Where the prolonged use of instruments, without strict antiseptic precautions, has occurred, the interior of the uterus is sure to be badly contused, so that the subsequent danger of sepsis is great. I would rather run the risk of the additional shock to the patient from removing the lacerated uterus than expose her to the certain risk of septicæmia by leaving it.

4. Though the objection made by Dr. Harris, that "a cervix split by laceration cannot be very well fitted for constriction, as the part below the wire may discharge septic matter into the abdominal cavity through the rent," is a good one, nevertheless, if the tear in the peritoneum is carefully closed, and the stump is properly constricted and shut off from the peritoneal cavity, I believe that there is less danger than there is when we trust to the suture alone, without constriction. Finally, with all respect for the opinion of such a weighty authority as Dr. Harris, who believes that it "would hardly be admissible" to subject a woman with a normal pelvis to "the unsexing operation of removing the lacerated uterus with the ovaries, as was done by Prévôt," it should be borne in mind that the laparotomist is sometimes called upon to do, and to do at once, what he believes is the best thing for the patient, without regard to established precedent or even to the ordinary rules of surgery. In the presence of a dreadful emergency we cannot reason as calmly and philosophically as we would in the library.

---

COLORED SPECTACLES.—Dr. Konigstein, while giving directions in his class on the uses and prescribing of spectacles, said that green glass as a protection against strong rays was worse than useless, and did more harm to a sensitive eye than good, as they allowed the yellow rays to be transmitted, and unnecessarily irritated the eye. As a protection against strong rays the blue or smoked glasses were the only real protection. The blue should be light, as a deep blue color produces a clear violet disk in the centre of the lens, which apparently corresponds to the fovea centralis, and by a protracted use of dark-blue spectacles the patient may become annoyed by the mosaic work of the fundus of the eye appearing before him. The phenomenon seems to be connected with the pigmenting changes in the macula lutea.—*Medical Press.*

## SOME CASES TREATED WITH HYDROGEN PEROXIDE.

By D. M. CAMMANN, M.D.,

NEW YORK.

HYDROGEN peroxide consists of water plus an atom of oxygen, thus forming the dioxide of hydrogen. This oxygen is in a somewhat loose form of combination, and readily separates itself when brought into contact with decaying organic matter or any substance for which it has an affinity, such as fresh roots of plants, ferments, pus, and other exudations from the animal body. This property makes it a powerful antiseptic and oxidizing agent. The peroxide of hydrogen is now known to be widely distributed in nature, it having been formerly mistaken for ozone, the tests for which are similar. It has been found in the air, in rain, in snow and hail, and in various kinds of forests, more especially among pines. The substance readily passes through animal membranes without undergoing noteworthy decomposition.[1] Whether it gives up its oxygen by direct addition to the blood is not quite certain, but from its known properties and from chemical observation of its effects such is probably the fact. It seems also to have some sedative effect upon the nervous system and to stimulate secretion from the liver and kidneys. It usually increases the appetite, but not markedly. Dr. Richardson, of London, first drew attention to the value of the drug, and recommended it in chronic and subacute rheumatism, chronic bronchitis with dyspnœa, in phthisis, and as a local application to gangrenous ulcers. He also strongly advocated its use in whooping-cough, asserting that it cuts short the disease most effectually. Lately it has been used quite extensively as a local application and as an inhalation in various cases with decided benefit. In diphtheria and other throat affections reports are in its favor.[2]

I have prescribed the peroxide of hydrogen in a considerable number of cases, mostly of pulmonary disease, in the past two years. Many of them have been decidedly benefited, and occasionally one has done better than with any other drug; but although I believe the peroxide to be of considerable value, the results attained were not such as had been hoped for from a drug which may be supposed to readily give up a share of its oxygen when brought into contact with the blood. Its value as a local application is undoubted. One case of whooping-cough in which it was given certainly recovered with remarkable rapidity. Little attention has been paid to its diuretic effect, yet it undoubtedly has considerable power in increasing the amount of urine.

I will give a few histories, and then a brief synopsis of the cases of which records have been kept. The patients took from five to twenty minims of the peroxide, most of them the larger dose, in a mixture of equal parts of hydrogen peroxide, glycerine, and water, from three to five times a day.

CASE I.—In one case of diphtheria in which ten minims were given four times daily, there was apparently little effect on the membrane from its use, but it seemed to bring some color into the cheeks. On account of the favorable reports of its effect in such cases I should be disposed to think that with larger doses the effect might have been more marked. A number of other drugs were used, including lime-water, lactic acid, tincture of iron, and chlorate of potassium, but none seemed to have much effect in clearing off the membrane, although the child eventually recovered.

CASE II.—In a case of whooping-cough the child took fifteen minims three or four times daily, with extremely satisfactory results. The paroxysms of coughing became less severe almost immediately, and in four or five days the cough almost ceased. In nine the child was so well that my attendance was no longer needed.

CASE III.—Bronchitis and subacute articular rheumatism. The woman had had several attacks of rheumatism in the past five or six years. She took peroxide for three weeks, with the results that the pains decreased rapidly and almost ceased after a few days.

CASE IV.—Mr. P. G——, aged forty-two; emphysema, and bronchitis with pleuritic adhesions; slight hypertrophy of the heart; May 12, 1888. Family history good; he has had cough for two or three years, which has steadily grown worse; has been too weak to work for the past ten days; has night-sweats; weight rapidly decreasing; appetite poor; appearance anæmic. Physical examination: Sinking in above the clavicles and below at outer third; some bulging of the chest below the clavicles at inner two-thirds; dulness on percussion under left clavicle; over both lungs respiration short, and expiration a little longer than inspiration; respiration feeble over right side in front; inspiration harsh under left clavicle; behind, inspiration harsh at both bases, otherwise respiration feeble over both lungs behind; apex-beat of the heart diffused, prolonged, and displaced to the left. ℞. Hydrogen peroxide, 5 minims, t.i.d.

May 15th.—Cough and expectoration less; does not feel any better; the weather has been unfavorable, which probably has something to do with his feelings.

May 24th.—Cough, expectoration, and dyspnœa less; night-sweats less frequent; urine not increased; increase hydrogen peroxide to 10 minims.

June 9th.—Cough steadily improving; expectoration less; passes an increased amount of urine; dyspnœa about the same; feels much less nervous; increase the peroxide to q.i.d.

June 16th.—Improved the same as in last note.

CASE V.—Mrs. M. B——, aged thirty-three; October 25, 1888. Family history: Her mother had lung trouble, otherwise family history is good. Previous history: Has been subject to frequent colds; has had cough for six weeks; expectoration abundant, greenish or yellowish; spat blood four days ago; night-sweats occasionally; chilly feelings and fever now and then, but not periodically; appetite poor; bowels open usually more than once a day; gives specific history. Physical examination: Dulness under left clavicle; sibilant respiration more or less over both lungs, most marked on the right side in front, coarse râles at both bases behind. ℞. Hydrogen peroxide, glycerine, aqua, āā ℥ j. M. S.: 3 j., t.i.d.

November 1st.—Cough and expectoration less; is nervous; not less so since taking the medicine; sleeps better; appetite much improved; urine increased; has a good deal of pain in the side, but none since taking the medicine.

November 17th.—Decided improvement.

November 24th.—Cough, expectoration, and dyspnœa less; appetite better; feels better; passes more water than before; feels less nervous; no pain now.

December 4th.—Improving.

An analysis of 19 cases shows that 11 were chronic bronchitis, most of them with more or less extensive pleuritic adhesions; 5 were cases of emphysema; 1 was pleuritic adhesions with valvular disease of the heart, and 1 was of phthisis. The latter did not improve under the peroxide, nor subsequently under other forms of treatment. All the others showed improvement, except one case of chronic bronchitis. By improvement I mean that some of the symptoms improved, but not in all cases was there improvement in every particular. Some of the cases might almost be recorded as cured, so great was the improvement. Most of the cases were so chronic that permanent cure could not be expected under any circumstances.

The longest time any case was under treatment was nearly four and a half months; the shortest time, five days; the average time of treatment was thirty-one days. The cough was improved in all. The expectoration was decreased in amount in all except 2; and in 1 of these it remained the same, and in 1 was increased. All the cases, except 1, that were troubled with dyspnœa were re-

[1] Mat. Med., Nothnagel and Rossbach.

[2] Hatfield: Archives of Pediatrics, February, 1888; I. N. Love: Weekly Medical Review, February 25, 1888.

lieved, most of them very markedly. The amount of urine was increased sufficiently in 10 cases for the patients to notice it themselves; in 8 cases no increase was noticed. The appetite improved in 14 cases. In 14 the patients were less nervous—would not start as easily at slight noises—and slept better.

That the peroxide of hydrogen is a drug of some value seems probable. Although I have had no brilliant results in any of my cases, except, perhaps, in the case of whooping-cough, still, some of the cases have been benefited, more apparently by the peroxide than by other drugs. The diuretic effect has not yet received much attention, but that it is a diuretic of considerable power in increasing the amount of urine is undoubtedly a fact.

19 East Thirty-third Street.

## THE MECHANICAL TREATMENT OF DROP-WRIST AND ALLIED PARALYSIS, WITH PRESENTATION OF A CASE.[1]

By V. P. GIBNEY, M.D.,

NEW YORK.

A LITTLE over two years ago, while visiting Mr. Hugh Owen Thomas, of Liverpool, I saw a rather queer device on a case of lead paralysis. It was simply an apparatus to keep the hand hyper-extended to the fullest possible limit. Mr. Thomas showed this with much pride, saying that it was the best treatment he had ever seen for drop-wrist. The explanation was that the extensor muscles were fully rested, while the flexors, which had become contracted by position, were overstretched. The idea seemed a very good one, and in January, 1889, I had an opportunity of putting the hands of a patient up in this position.

She was thirty years of age, and was first taken sick in May, 1888. She thought that her sickness was due to drinking water after its long standing in pipes. There was no other explanation of her illness so far as we have been able to learn. Her symptoms were cramps in the stomach, followed by diarrhœa and vomiting. This condition of things lasted for about three weeks. A physician who was called to attend her this time gave her some medicine to control the diarrhœa and vomiting. A month later she began to experience a pricking sensation in both hands and feet, followed by numbness, with loss of power in the hands. She tells me that she was unable to hold a pen in the right hand while writing. During this whole time she had much pain in the stomach, with loss of appetite. All this occurred in the country.

She appeared at the New York Dispensary some time in the summer of 1888, and was told there by the physician who saw her case that it would require one year to get well. She continued there in treatment for four weeks, and, becoming discouraged, was admitted to Bellevue Hospital, and for the first time she was told that she had lead paralysis. She remained in the hospital six weeks, taking medicine three times a day, a double dose at night. She had, at the same time, electricity three times a week. At the end of this time her pains began to diminish, her general strength increased, but she does not admit that her wrist-drop was any better.

She was transferred to the Randall's Island Homœopathic Hospital a little later. She got a leave of absence one day, and came to see me on the 8th of January, 1889, when I found her with complete palsy of the extensor group of muscles, both wrists, but with considerable power to flex. I did not make any electrical examination, but proceeded at once to put her up in the apparatus which I show this evening. I secured the appliances with a solid plaster-of-Paris bandage, hands and fingers fully hyper-extended. She went back to the Island and was not received very favorably because of her helplessness. However, some one of the attendants fed her, and on the 8th of February, one month later, I removed the dressing for examination, finding the patient able to extend both hands to 180 degrees, but not able to hyper-extend any. I reapplied the bandage, and on the 19th of February it was found that the hand did not drop any except after a few minutes' attempt at extension.

After leaving Randall's Island Hospital, and while she was wearing the splint, that is, the latter part of February, she was admitted to the Presbyterian Hospital and remained four weeks, and was discharged because she insisted on keeping her plaster on. This was her own report. At all events, the splints were removed some time in March or April, and I did not see her again until the 22d of August, when the cure was complete. I saw her again on the 3d of October, and I do not discover any defect in her hands. She came then to return the springs, and to thank me for the relief she had obtained, and it was quite willingly that she came here this evening for your inspection.

I have for a long time been very fond of this method of treating external paralysis about the foot. I aim always to over-correct the deformity, and retain this position as long as I possibly can. I am at present employing this method in one or two hemiplegics who have drop-wrist and some spasm of the flexors, but am not prepared to report results. The plan commends itself, I think, on account of its simplicity, and the result in this special case, I think, is unquestionable.

[1] A paper read before the Practitioners' Society, October 4, 1889.

## Progress of Medical Science.

THE MOST RECENT ANTISEPTIC TREATMENT OF WOUNDS.—This subject has recently been again discussed in the *Centralblatt für Chirurgie*, and the methods of Von Bergmann, Mikulicz, and Schmid, described. From a résumé published in the October number of the *American Journal of the Medical Sciences*, we learn that Von Bergmann requires the patient to be thoroughly cleansed with soap in a warm bath, after which he is brought immediately to the operating-table, shaved, washed with alcohol, or with ether, if necessary; and, finally, the field of operation is washed with bichloride of mercury, 1 : 500, and surrounded with towels wet in the same solution. The operating-table is covered by a sterilized cloth. Operators and assistants cleanse their hands according to the method pursued in regard to the operative field. Everything which can come in contact with the patient—clothing, scrubbing-brush, etc.—is previously sterilized by superheated steam, except the sponges, which are washed in boiled water and soaked in bichloride solution. The instruments are sterilized by carbolic lotion. For ligatures and buried sutures sublimate catgut is used. For superficial sutures, sterilized silk is employed. Since the air of the ordinary clinic-room is rich in pathogenic organisms, the wound should be carefully protected during operation by sublimate compresses. Absolute hæmostasis is insisted upon, even slight oozing in connective tissue or bone-cavities being checked. The wound is then irrigated with 1 : 2,000 sublimate solution, dried by means of sterile gauze compresses, drained, closed, and dressed with sterile gauze containing no antiseptic, absorbent cotton, and a moss pillow. These dressings are sterilized by means of heat. If the wound is already infected, it should be opened freely, cleansed, drained and counter-drained, packed loosely with iodoform gauze, and dressed with sterilized gauze and the moss pillow. The superficial dressing is changed, but the packing is not disturbed unless it becomes wet and dripping. In that case it is removed and a drainage-tube substituted for it. After operations which leave the surgeon not quite sure as to the absence of infective matter in the tissues, or in case the bleeding has not been thoroughly checked, or where the wound is in a region difficult to keep germ-free, Von Bergmann com-

mands primary iodoform gauze tamponade with secondary suture. Finally, after resections and arthrectomies performed for the cure of tubercular arthritis, the wound should be treated with ten per cent. iodoform ether, and tamponed with iodoform gauze; the latter to be removed in two days and the wound sutured without providing for drainage. In contrast to Von Bergmann's treatment, Mikulicz commands, in many cases, Schede's method of obtaining healing (moist blood-clot). The ordinary chemical antiseptics are used. Sponges are discarded for wads of sublimate cotton wrapped in mull, and kept in sublimate lotion. During the operation the wound is washed out with sublimate solution every five minutes. All bleeding vessels are tied, the wound finally thoroughly irrigated, first with five per cent. carbolic solution, finally with the bichloride of mercury lotion, closed by relaxation sutures of silk or silver and a continuous catgut suture, and dressed with protective or gutta-percha tissue, ten per cent. iodoform gauze wrung out in five per cent. carbolic lotion, and a moss pillow. In two places a little space is allowed between the sutures so that any excess of blood can escape. If there is a cavity left at the operation which cannot be closed by approximation of the wound-surfaces, the space for the escape of blood must be left at the highest portion of the superficial incision. The bandage is usually not changed till the wound is entirely healed. After operation upon tubercular inflammations, Mikulicz recommends iodoform gauze, tamponade, and secondary suture. Of the one hundred and sixty major cases treated by this method, Mikulicz has lost only one. This patient died sixteen days after operation of consumption. In only three cases did pain and high temperature force him prematurely to change the dressing. Schmid completely closes his wounds immediately and discards drainage. Should symptoms denoting tension or suppuration appear, he removes the dressing, takes out a stitch, and opens the wound somewhat. The site of operation is covered for twelve hours with moist sublimate compresses, and is finally washed with ether and sublimate solution. In every pause of the operation the wound is covered by sublimate sponges. There is no irrigation and the minimum of sponging. Most careful attention is given to checking the bleeding, after which the wound is flushed with bichloride solution, dried, dusted lightly with iodoform, and approximated throughout its whole extent. A compression sponge is now applied, iodoform, mull, and a moss pillow. The dressing is completed by a pressure bandage very firmly applied, which can be loosened if painful in twenty-four hours. In wounds where pressure is not necessary, salicylated collodion painted over the skin sutures will prove a sufficient dressing. For infected wounds, Schmid advises free opening, drainage by means of iodoform gauze, and antiseptic poultices.

THE BEHAVIOR OF THE GERMS OF CHOLERA, TYPHOID FEVER, AND TUBERCULOSIS IN MILK, BUTTER, WHEY, AND CHEESE.—Among the numerous labors of the Reichsgesundheitsamt has been that of determining the behavior of certain germs of disease in various articles of food. Milk is one of the most common articles of diet, and one of the health-office collaborators, L. Heim, of Würzburg, has lately concluded a lengthened inquiry into the relations of the bacilli of tuberculosis, cholera, and typhoid fever to it, and its products, whey, butter, and cheese. That milk is a favorite medium for dissemination of disease is well known, and Koch, among others, has shown that it is peculiarly adapted for this purpose. As regards cholera, the germs of the disease were still viable after remaining for six days in milk that had undergone no antisepticizing processes; in milk of the same character that had been kept in the ice-chest, on the other hand, no living bacteria were found at the end of three days. This part of the inquiry shows that cholera bacteria remain active in fresh milk the whole length of time it is customary to keep it, and that they do not lose their dangerous quality for some days after the milk has become sour. The same germs were found active under some circumstances even at the end of a month. In ordinary strong cheese they did not retain their viability over a day, neither did they in unripe cheese. The bacilli of typhoid were alive and capable of development in milk at the end of thirty-five days, but no longer so at the end of forty-eight days; in butter they remained active between three and four weeks; in cheese only three days, and in whey only during the first day. Tubercle bacilli remained capable of development for ten days in fresh milk; in milk gradually undergoing decomposition they lost their power in a period varying between ten days and four weeks. In butter, on the other hand, they retained their full power at the end of four weeks; in whey and cheese after two weeks, but not after four weeks. The practical importance of the investigations is so obvious as scarcely to need pointing out, and their bearing on the use of milk, the preservation, carriage, preparation, and sale of it and its products is equally obvious. Something has been done, much remains to be done, to stop the ravages of disease, and the labors of Dr. Heim are another step forward.—Berlin Correspondence, *Medical Press.*

ŒDEMA OF THE BRAIN.—Professor Huguenin distinguishes two varieties of œdema of the brain—the inflammatory and the non-inflammatory. Inflammatory œdema, or diffuse encephalitis, is observed in perforating wounds of the skull with any kind of injuries to, or crushing of, the brain substance; in brain tumor, as soon as a central necrotic softening takes place in it and approaches the periphery; in abscess; in infectious diseases; and less often in hemorrhages and hemorrhagic infarct. As regards uninflammatory œdema, opinions have been at variance whether the peculiar arrangement of the circulation within the skull would permit of the exudation of sufficient serous fluid to produce a rapid and fatal pressure on the brain. As the result of his anatomical studies, the author takes the view that disturbances of the circulation in intracranial diseases can produce no fatal œdema as long as the vessels and the conditions within the skull are normal; but that these disturbances, for whose adjustment there are fully satisfactory arrangements under normal conditions, can produce fatal œdema, if previously existing changes are present in the skull or brain. These changes are, obliteration of the ports of exit for the lymph, moderate chronic pressure on the brain through contraction in the size of the skull, or, much more, through arrest of its development, diseases of the brain which produce a greater or lesser degree of pressure. Theoretical considerations would explain the so-called congestive œdema of the brain, *i.e.*, the effusion of serum under the membranes, into the brain, and into the ventricles, as being due to a hyperæmia of relaxation, as it is termed, of the vessels of the brain, so that more blood streams through them. At first this occurs with greater rapidity on account of the diminished resistance in smaller arteries; so that instead of the vessels bearing thirty per cent. and the surrounding parts seventy per cent. of the pressure, as in the normal condition, the vessel walls do not bear more than ten per cent., and the surrounding parts receive about ninety per cent. The pressure exerts itself against all distensible parts, such as the fontanelles and the vertebral ligaments, which yield as far as they are able. At the same time there is an increased efflux of the cerebro-spinal liquid through its normal channels, and this may serve to relieve the pressure. If, however, the tension of the blood-vessel walls diminishes, and the pressure of the cerebro-spinal liquid exceeds ninety per cent., this efflux is of no avail. The pressure becomes so great that compression of the capillaries takes place, and, thereby, a general ob struction to the circulation, with consequent stagnation of blood in the dilated arteries, and fall of pressure in the veins. The fluid constituents of the blood then leave the vessels, collect in the sub-pial space, brain, and ventricles, and the œdema of the brain is established. This supposition explains the congestive œdema which is said to be

common in children, and only rarely to occur in adults. Not in accord with this is the fact that children, unlike adults, have *two* arrangements for compensation—the fontanelles and the ligaments; and still less do those experiments accord, which show that even a very considerable increase of pressure, artificially produced, does not provoke œdema of the brain. As a result of his studies on his own cases, the author comes to the following conclusions: 1. Those children which were supposed to have died of hyperæmia of the brain, œdema, or slight hydrocephalus, were always found to have had a beginning meningitis, usually of an infectious nature, *i.e.*, a streptococcus meningitis. What, therefore, the author would formerly have regarded as a congestive œdema, he would now designate as streptococcus meningitis, more or less developed. 2. On the other hand, fatal œdema of the brain, of a congestive nature, does occur in children, but only under particular circumstances. The first of these is chronic meningitis, which produces obliteration of the channels of exit from the sub-pial space, and obliteration of the Paccionian granulations. In adults, also, chronic meningitis may play a similar *rôle*. The second factor in the production of fatal congestive œdema is present when a pressure on the brain is already in existence, which is, perhaps, already nearly as great as can be endured by the organ. If now any irritation produce a hyperæmia of relaxation, its action will be very rapid, since the brain possesses scarcely any further power to yield to pressure. To this class belong: 1. Fatal cases of œdema of the brain due to lack of power of the organ to expand; this being the result of a too early ossification of the sutures. 2. Fatal cases of œdema of the brain occurring after the intra-cranial space had already been diminished by some disease of the brain. Here belong three categories of affections: acute hemorrhage, tumor, and abscess in the inner parts of the brain, which have not yet produced a meningitis; finally, a traumatism of the brain not communicating with the atmosphere.—*The American Journal of the Medical Sciences*, October, 1889.

Œdema as a Diagnostic Sign in Carcinoma of the Stomach.—Dr. Baert, of Brussels, calls attention to the frequency with which œdema of the ankles is met with in cancer after it has lasted a few months—a diagnostic aid which is by no means new, but is, he thinks, in danger of being too much overlooked at the present day (*The Lancet*). He gives a number of cases recently occurring in the various hospitals in Brussels in which œdema was present. In one of these cases the œdema came on as early as three months after the first symptoms of the affection made their appearance; in two other cases it was noticed after four months; but in most of the other instances it was delayed till the lapse of from six months to a year after the onset. In one case, where there was no evident cause to which to attribute the loss of appetite and the wasting complained of by the patient, Professor Carpenter, noticing some œdema of the ankle, diagnosed carcinoma of the stomach, and found his diagnosis confirmed by the appearance a month afterward of all the usual signs of the affection. Several of the cases presented a marked increase in the nitrogen excreted in the urine. With regard to the deficiency or absence of hydrochloric acid in the stomach, in cancer of that organ, M. Baert admits that it is usual, but agrees with Wolff and Ewald in saying that this sign is by no means peculiar to cancer, as it is found in other gastric affections.

Syphilis of the Intestines.—Dr. Barié points out that little or no attention has been devoted to the study of syphilitic affections of the intestine, and he suggests that their supposed rarity may in reality be due to a lack of knowledge of the subject. He has collected a number of observations in which the subjects of syphilis, either hereditary or acquired, exhibited undoubted syphilitic lesions of one or other part of the intestines, sometimes simply enlargement of the Peyer's patches, more frequently, numerous ulcerated patches. He mentions more particularly the case of a woman, aged thirty-two, who was admitted into a hospital in a state of stupor, with a history of severe headache and general fatigue of a month's duration. The abdomen was tympanitic, painful on pressure, especially in the right iliac fossa. Profuse yellow fetid stools. Notwithstanding the typhoid symptoms no rash could be discovered. Coma supervened, followed by death. *Post-mortem* a number of ulcerations were found in the neighborhood of the cæcum, with irregular excavated borders, the base being a whitish-gray, and covered with purulent matters. Two other ulcers were discovered in the transverse colon, the sigmoid flexure, and the descending colon. The mesenteric glands were not appreciably enlarged. The diagnosis of the syphilitic origin of these ulcers was arrived at by a process of elimination. He points out that intestinal syphilis attacks the terminal portion of the small and the large intestine in preference, its effects being localized in the collections of lymphoid tissue. It produces ulcers with thickened borders, filled with a yellow puriform material, and all the coats of the gut are involved in the morbid process. Clinically, the affection gives rise to an obstinate and profuse diarrhœa, the stools being yellow, fetid, and, from time to time, sanguinolent. In some cases the diarrhœa brings about emaciation, cachexia, and death from exhaustion, but in others it takes on an acute form, and then markedly resembles typhoid fever. In the latter, the differential diagnosis is very difficult. Perforation, with consequent peritonitis, is a frequent complication.—*The London Medical Recorder.*

Treatment of Phthiriasis Pubis.— In one of the weekly meetings of the physicians of the St. Louis Hospital, Paris, the question of treatment for pediculi pubis was discussed. Dr. Besnier remarked that it is an easy matter to get rid of pediculi vestimenti, and even of lice in the head, while those which inhabit the pubic region are relatively difficult to destroy. An excellent method consists in giving a bath of an hour's duration, the water containing ten grammes of corrosive sublimate which has been dissolved in alcohol. The old-time frictions with mercurial ointment have been almost entirely abandoned, because of the irritant phenomena to which they may give rise. When gray ointment is employed it is best not to leave it upon the skin for more than two hours, for fear of producing an erythema, pustulation, and salivation. At the present time it is preferable to apply, morning and night for two or three days, a lotion containing corrosive sublimate dissolved in alcohol, in the strength of 1 to 200 or 1 to 300. The hairs are then to be washed with hot vinegar, and the nits, thus softened, are readily removed with a fine comb. It is furthermore necessary to exercise a close scrutiny for several days to prevent a recurrence. Dr. Hallopeau employs only frictions with camphorated alcohol for the cure of all forms of pediculi. In three days he thus secures a complete cure. Professor Fournier insists in his clinics upon the frequency of pediculi pubis in the lower classes, where their presence is almost always ignored, showing how little itching they occasion in the majority of cases. As soon, however, as we inform the patients of their condition they are, on the other hand, much annoyed by the itching. Another topical application in phthiriasis and in pruritus is phenic acid.—*Journal of Anatomy and Genito-Urinary Diseases*, September, 1889.

Spermine.—*Spermine* is an alkaloid found in testicular juice, in the gray matter of the brain, in eggs, oysters, lampreys, fish ova and milt, also in the products of all atonic mucous membranes. It also appears in the sputa of senile and acute bronchitis, in the expectoration of phthisis, and of emphysema with catarrh, and the spleen and circulation of anæmics and leucocythæmics. The *hydrochlorate of spermine*, in a dose of one-fortieth of a grain, injected subcutaneously in a dog of thirteen pounds, produced marked physical and mental activity, and powerful and prolonged stimulation of the genital system.—*Medical Age.*

## THE HARD LOT OF THE ACTING ASSISTANT SURGEON.

THE Association of Acting Assistant Surgeons of the U. S. A., which was formed about a year ago, has as one of its main objects the bettering of the position of those who are now serving the Government in that capacity. The first step, of course, toward righting a wrong is to make the wrong known, and we think many of our readers will be astonished to learn what the duties are of the acting assistant surgeon in our army, and how his services are requited by the United States Government. It is safe to say that one would have to look far before finding a more poorly paid body of professional men than the fifty "contract surgeons" at present in the employ of the Government. Let us see for a moment what is required of the acting assistant surgeon and we shall then be in a position to judge whether the pay and honor that he receives are a sufficient recompense for his labors. We are indebted to Dr. W. Thornton Parker, of Newport, Recorder of the Association, for much information on this subject.

The requirements for admission to this branch of the service, if such it can be called, are sufficiently stringent to prevent any but competent physicians from obtaining an appointment. One must first apply to the Surgeon-General for an invitation to appear before a medical examining board. This request must be in the applicant's own handwriting, must contain a statement of his age and birthplace, and must be accompanied by testimonials as to his moral character. Next the physical qualifications of the candidate and his fitness to undergo any probable hardships of field service or exposure in any climate or at any season of the year must be rigidly tested by the board, and a favorable report will not be made in any case in which this is doubtful. The oral examination is in the branches taught in the common schools and the candidate must satisfy the board that he has a good knowledge of orthography, grammar, and the fundamental rules of arithmetic, including operations with fractions, and that he has a fair acquaintance with geography and history of the United States. His examination will not be continued further if he be found deficient in these branches. There is, further, an oral examination in anatomy, surgery, practice of medicine, obstetrics, and diseases of women and children, therapeutics, including tests and antidotes for poisons and the writing and compounding of extemporaneous prescriptions. One question each upon anatomy, surgery, practice of medicine, and obstetrics will also be given to the candidate in writing, and his written answers to the same are preserved as part of his record and transmitted to the Surgeon-General's office.

Appointments are made from among the successful candidates according to their standing in this examination.

After their appointment the acting assistant surgeons have the same duties to perform as those with commissions who enjoy the rank and pay of first-lieutenants, captains, and majors, but their standing and their position in the army are very different. Their pay is about one hundred dollars per month, and their rank is—nothing. In one respect they are worse off than the humblest employee of the Government, for they are not subject to the civil service rules, and are liable to dismissal at any time, without cause. A clerk in one of the departments at Washington is allowed a certain vacation every year, but an acting assistant surgeon in the army is paid only for actual service rendered. If he is incapacitated for work by sickness, contracted, it may be, in the discharge of his duty, his pay stops. Or if he feels the need of a brief rest, after several years of continuous service, he must take it at his own expense, and at the sacrifice of his salary for the entire period. But even this is not all. No matter how long he may have served his country his pay remains the same, and finally, when, broken down by age and long service, he finds himself obliged to give up work, he is let go without so much as a "thank you," and must henceforth shift for himself as best he can. And beyond and above all this material hardship, these men—cultivated professional gentlemen—are forced to submit to many indignities against which a self-respecting mechanic would rebel. But on this point we cannot dwell now, and will briefly consider the means by which it is hoped to ameliorate the lot of the contract surgeon.

The demands of the Association can certainly not be regarded as extravagant or unreasonable. As announced in a recently issued circular, it is proposed to present a "petition signed by the acting assistant surgeons, and endorsed by assistant surgeons, surgeons, and others who may favor the same, to the Military Committee of the next Congress, praying that acting assistant surgeons of the army (now serving), many of whom have served long and faithfully, performing all the professional duties of commissioned surgeons, and many of whom are past the age permitting them to apply for examination for commissions as first-lieutenants in the medical corps, be commissioned assistant surgeons, with the rank of second-lieutenant of cavalry, not to be in the line of promotion, the pay (that of second-lieutenant) not to be increased, and to be allowed forage for one horse; that at the expiration of the regular full term of service, or on account of disability, they be placed on the retired list of the army."

We have only one criticism to offer in regard to this proposed petition, and that is, that the Association is far too modest in its request to Congress. The rank and pay of a first-lieutenant would be none too much to ask for, and would probably be not much more difficult to obtain. The proposed petition is regarded with favor by many of the older officers of the army, and we hope that the Surgeon-General, whose endorsement would naturally carry much weight, will also, at the proper time, unite his

influence with that of others who are endeavoring to obtain this measure of justice for a most deserving body of physicians.

### WILL THE TIME EVER COME?

As we have read the remarkable work of Mr. Edward Bellamy, "Looking Backward," we have felt a certain pride that the chief spokesman is portrayed as a physician. We are not to infer that this was the chief idea of the writer in making this selection, but there is, nevertheless, conveyed a delicate compliment in the choice. We should feel a certain degree of disappointment did we believe the character of Dr. Leete to be purely an ideal one for the present age, for it is our firm conviction that some of the most noble men alive to-day are engaged in the practice of medicine. They may not be taking a prominent part in discussing social and industrial problems, but they come in contact with all sorts and conditions of men, and can make no small contribution to the data which form the basis of such discussions. It is no wonder, therefore, that Mr. Bellamy has chosen the medical calling as that one to be followed by his exponent of the ideas of one hundred years from to day.

It is very easy to follow out in imagination another chapter along this line of altruistic development. We can imagine Dr. Leete telling Mr. Julian West how hospitals, dispensaries, and medical societies were managed in the times in which he lived. There will be no code, for all men will be properly educated, and be gentlemen. With perfect confidence does the family practitioner refer his patient to the specialist, well knowing that the latter will send him back again, with diagnosis stated and a line of treatment suggested. There will be no rivalry to be appointed physicians to the new hospital, for each one chosen will offer to resign in favor of his unsuccessful competitor, and the only possible embarrassment will come from the excess of self-abnegation. The occupation of the consequential and patronizing hospital manager will be a lost art. Contributors to medical journals will never write on both sides of the paper, will *never* send their manuscripts rolled up, nor desire reprints and extra copies, and will wait their turn for publication. Their thoughts will be condensed, and their great aim will be to say as much as possible in the fewest number of words. As all men will be educated, and the private research of each be made public property, the opinion of the retiring, common-sense, professional neighbor will be as worthy of at least as courteous a reception as that of some unknown Herr Professor, with an unpronounceable name, from the middle of one of the southern provinces of Austria.

Also, physicians will be represented on the governing boards of what few medical charities may remain, for the new industrial system, with its consequent abolition of poverty, will render them entirely unnecessary. The dispensary "rounder" will rival the mound-builders as an effete historical curiosity. The "able-to-pay patient" will have been evoluted out of existence, and while the supply of clinical material may be disappointingly small to some of our great men, the comfort of the rank and file of the profession will be greatly enhanced. State examining boards will exist everywhere, and the so-called generous and unselfish rivalry between the few medical schools that are then needed will cease.

We will not enlarge on this theme, nor can we promise that the elixir vitæ, or, as our Western contemporaries call it, the Methuselah Cocktail, offers any prospect of our being enabled to live till the Golden Age.

But, seriously, when one comes to read Mr. Bellamy's book, he realizes how sadly the times are out of joint, so far as social and industrial questions are concerned. His illustration of the stage-coach in the opening chapter is grim, but most sorrowfully truthful. His Utopia does not seem by any means a purely imaginative one, though the very antipodes of the present age. "Looking Backward" should be read by every physician. It shows one's general social duty, regardless of his calling. It contains a warning for the thoughtless rich, and a promise for the unfortunate but honest poor. To every reader will it suggest new thoughts, and in everyone inspire new hopes, and loftier ambitions. The author's idea of "nationalism" may be chimerical, but his motive is praiseworthy.

### OUR ILLUSTRATION PLATE OF SMALL-POX.

In this issue we present a fourth of the series of eruptive diseases from Morrow's "Atlas of Skin Diseases." In the three figures we have presented the leading types of the variolous eruptions. As small-pox is, fortunately, not a common disease, but, unfortunately, a very contagious one, it becomes every practitioner to be on the alert for a correct diagnosis in the earlier stages, in order more particularly that the proper preventive measures may be taken against the spread of the malady. The plates should be studied in connection with a detailed account of the symptoms, which latter can be found in any of the text-books on practical medicine.

The figures in the plates show very truthfully and artistically the different degrees and varieties of efflorescence, viz., the papular and vesicular over the entire body, the umbilicated on the foot, and the confluent variety of the mature pustules on the face.

A careful inspection of these truthful and well-executed pictures cannot fail, we believe, to interest the large number of our readers who are apt during the season to meet with a case.

### COMPARATIVE VALUE OF ANTIPYRIN, ANTIFEBRIN, AND PHENACETIN.

While the regular and systematic use of antipyretic drugs in continued fevers is no longer to be considered a safe or wise practice, yet their employment in ephemeral fevers, in acute febrile attacks, heat-stroke, and very high temperatures in all conditions, is often stringently indicated. A study of the comparative value of antipyrin, antifebrin, and phenacetin, recently made by Surgeon-Major A. Crombie, of Calcutta (*The Practitioner*), gives us some facts of practical interest.

Dr. Crombie's observations are very clearly summarized as follows:

1. As regards efficacy, antipyrin comes first, and there is little to choose between antifebrin and phenacetin.

2. That as regards safety the advantage lies with phenacetin. A subnormal temperature never resulted from the use of that drug. Dr. Crombie had seen subnormal temperatures as the result of the use of antifebrin, but never collapse, which he had once seen from the use of antipyrin.

3. As regards rapidity of action, antipyrin, probably on account of its solubility, comes first, antifebrin second, phenacetin third. The fall after the use of phenacetin is more gradual, and the minimum is not reached for three, four, or even five hours after the administration of the drug.

4. As regards duration of effect the advantage lies with phenacetin.

5. As regards certainty of action, Dr. Crombie quotes them in the same order as that of rapidity—antipyrin, antifebrin, phenacetin. Phenacetin should be prescribed either in powder or in lozenges which are soft and friable.

6. As regards inconveniences, in the climate of India phenacetin is followed by just as profuse sweating as either antifebrin or antipyrin, and this, to his mind, is the great drawback in the use of antipyretics, patients having to change their clothing once or twice in a night after the use of any of these drugs. Whether or not an antipyretic will yet be found which will be capable of safely reducing abnormal temperature without causing profuse perspiration remains to be seen, but as yet we do not possess one.

Dr. Crombie adds that there is one peculiarity which phenacetin does not share with the other antipyretics. He alludes to a soothing and soporific effect which it undoubtedly possesses, so much so that in cases of slight feverishness accompanied by insomnia and great restlessness small doses of three or four grains of phenacetin, not sufficient, in India at least, to produce perceptible diaphoresis, insure a quiet, peaceful, and sleepful night, with no headache in the morning.

In conclusion, he says that in heat apoplexy, sunstroke, and hyperpyrexia generally, antipyrin is indicated. In temperatures of 103° to 105° antifebrin or phenacetin, in temperatures below 103° the preference should be given to phenacetin.

## News of the Week.

An Important Precedent for the Association of American Physicians and Surgeons.—Dr. C. H. Mastin, of Mobile, in declining the office of president of this association, at the recent meeting of the executive committee, expressed the opinion that someone not a member of the committee should be selected for this high office. For obvious reasons this is a valuable precedent, and is fittingly set by one who is an illustrious example of Southern chivalry and modesty.

Woman's Hospital of the State of New York.—Drs. Horace T. Hanks and Bache Emmet have been unanimously appointed as Visiting Surgeons to fill the vacancies occasioned by the death of Dr. James B. Hunter and the resignation of Dr. Charles Carroll Lee.

Ohio State Sanitary Association.—The seventh annual meeting will be held in the hall of the Young Men's Christian Association, Dayton, O, November 21 and 22, 1889.

Medical Legislators.—Of the 557 members returned at the recent general elections to serve in the French Chamber of Deputies, 48 are doctors of medicine, 4 are druggists, 1 is a dentist, and 1 a veterinarian.

A New Disease—Confectioners' Fingers.—Dr. Rodriguez Mendez, Professor of Hygiene in the Medical Faculty of Barcelona, has just published in a new Spanish journal, *La Medicina Prdctica*, some notes of a case of a peculiar affection of the fingers and nails which appears to have been due to the patient's trade, that of a confectioner (*The Lancet*). Poncet, of Paris, and Albertin, of Lyons, have also observed the existence of this affection among those who are engaged in the calling of a confec tioner. Dr. Mendez's patient was a man about forty years of age. His trouble was a combination of onychia and paronychia, caused by immersing the hand in hot and cold syrups.

Rich Men's Dispensaries.—The Johns Hopkins Hospital is found to be a not unmixed blessing to the medical profession of Baltimore. The *Maryland Medical Journal* says that, in the last six months, five thousand dispensary patients have been treated there, and that these consist largely of persons who used to go to a physician. Much the same kind of story is told by physicians of this city, regarding the Vanderbilt and the Presbyterian Dispensaries.

New York Neurological Society.—The commission appointed two and a half years ago to investigate the relation between disturbances of the ocular muscles and functional nervous diseases will make its report at the stated meeting on Tuesday next at the Academy of Medicine.

Civil Service Reform.—It is well known that the state of civil service reform in New York is not what its friends could wish it to be; and that it would be well if some clear presentment of the facts were made by those who have had occasion to know best as to the details and as to abuses—in the interests of better sanitation. It looks as if the only answer to the question was, "What are you going to do about it?"

An Interviewer in the Guise of a Patient.—A young woman, a reporter on a sensational daily paper of this city, paid a visit to a number of physicians recently in the guise of a patient suffering from headache. Every detail of her various interviews, the diagnosis made, prescriptions and advice given, and fees charged, were subsequently written out and published in a most sensational way. The differences in diagnosis and advice were considerable and were made to appear rather ridiculous, as might easily be done by a person presenting only a subjective symptom. The performance, we think, was a great piece of impertinence and one in which reputable journals or journalists would not be concerned. The physician is under bonds to respect the confidence of his patients and the obligation is almost as great that the patient should not go and gabble to the public personal items regarding the physician.

Death of Dr. Moses D. Carbee.—At Haverhill, N. H., October 23d, of diphtheria contracted in practice, Moses D. Carbee, M.D., aged forty-two years. Dr. Carbee was graduated from the University of Vermont in 1873, and for fifteen years had been honored and loved in Haverhill and the surrounding country as a skilful and faithful physician, and an unfailingly kind and sympathetic friend.

Dr. Pietro Laura, one of the leading physicians of Italy, died recently at Genoa in the seventieth year of his age.

THE STRING IS PULLED AND THE BAND STOPS ITS PLAY.—The physicians of the Eastern Dispensary, having been much annoyed during their auscultatory practices by a neighboring museum band, have made an arrangement with the latter by means of a connected signal-bell to stop the music during chest examinations. Statistics show, however, that the bell is rung but one and a half times daily. Our good brothers are evidently not quite up to their opportunities. How much the latter would be appreciated by their fellow-practitioners who could shut off the "little German band" by the pull of a string, or by allowing the patellar reflex a free play on the sidewalk.

THE LATE DR. JAMES B. HUNTER.—At a meeting of the Practitioners' Society of New York, October 4, 1889, it was *Resolved*, That the members of this Society express their deep regret at the sudden and untimely death of their late colleague, Dr. James B. Hunter. They recall the fact that he was one of the founders of the Society, that he was its first President, and always took an especial interest in the success of its work, to which he made practical and original contributions. Dr. Hunter was esteemed for his social qualities as well as for his eminence as a physician; and in his unfortunate death the members feel a sense of great personal bereavement.

W. T. BULL,
R. F. WEIR,
CHARLES L. DANA, } *Committee.*

PROFESSIONAL SERVICES OBLIGATORY.—A French court has recently decided that physicians are bound to give in good faith their professional services when solicited by those who represent the law.

AN EXCELLENT DRAWING by Albrecht Dürer was found lately in a medical book in a library at Zwickau. It represents a dying man sitting behind a stove and Death threatening to extinguish the light of life, while a female form personifying the Art of Healing approaches to save.

THE GERMAN IMPERIAL MINISTRY OF THE INTERIOR has made a grant of $20,000 toward the expenses of the International Medical Congress to be held in Berlin in 1890.

THE TRANSPORTATION OF DEAD BODIES.—The Association of Baggagemen, which recently met in Detroit, passed resolutions insisting that all bodies of persons dead from contagious diseases, held for transportation, must be properly prepared for shipment by being wrapped in sheets saturated with mercuric chloride and placed in metallic caskets, to prevent the spread of disease.

THE DOCTOR'S EARNINGS.—According to Dr. Jarvis' tables, the average of the lives of physicians is fifty-six years. If you begin practice at twenty-four, your active-life prospect will be thirty-two years, and from a thousand to fifteen hundred dollars will represent your average yearly income. Now, were you (through God's mercy) to practise these thirty-two years without losing a single day, and collect (say) eight dollars every day of the time, you would receive but $93,440. Deduct from that amount your expenses for yourself and your family, your horses, carriages, books, periodicals, and instruments; your taxes, insurance, and a multitude of other items for the whole thirty-two years (11,680 days), and then, so far from being rich . . . you would have but little, very little, left to support you after you naturally reach the down-hill of life, or are broken down in health and faculties deteriorated, and in need of a physician yourself, through worry, anxiety, and fatigue in the discharge of your duty.—DR. CATHELL, in last Edition of *Physician Himself*.

INOCULATING CANCER.—At a meeting of the Gesellschaft der Aerzte in Zurich, Dr. Hanau stated that he had succeeded in inoculating carcinoma from rat to rat. On November 28, 1888, he excised two pieces of a carcinomatous lymphatic gland from a female rat with malignant disease of the vulva, and transplanted these into the right half of the scrotum in two old male rats. One of the latter died on January 14, 1889. The necropsy revealed a generalized "carcinosis" of the peritoneum (including the great and small omentum). In the other, which was killed on January 25th, there were found two typical cancroid nodules (one 2.5 millimetres in diameter, the other the size of a pea) on the gubernaculum testis and the cauda of the epididymis. The transplanted malignant growths proved to have precisely the same structure as those which had spontaneously originated in the first animal. According to Dr. Hanau's theory, the cancroid infection should be attributed to the agency of live epithelial cells, and not to any pathogenic microbes. Another series of the author's experiments on the artificial production of cancer in rats by means of a prolonged local use of such irritant substances as tar, etc., gave negative results. The application caused an eczematous rash, with some infiltration of the corium, but no malignant disease.

A SIMPLE REMEDY FOR THRUSH AND SORDES, writes Dr. W. T. Ord in *The Lancet*, is equal parts of lotio nigra and glycerine mixed. He adds: "I attribute its action to the germicidal power of the mercury. The quantity used is so small as to be quite harmless. Another condition in which I have found the same lotion invaluable is in that of the sordes which collect so abundantly on the teeth, lips, and tongue in many cases of enteric fever. It cleans these parts as if by magic, and renders that unpleasant process known as "scraping the tongue" quite unnecessary. It may also with advantage be painted over the fauces, etc., in those unhealthy conditions of the throat which are so common in typhoid. I tried it in one case of catarrhal stomatitis, but it had no effect, whereas chlorate of potash effected an immediate cure. Also, in the sordes of advanced phthisis it seems to be of no use."

SOME REMARKS ON HYPNOTISM.—Dr. Hunter McGuire, of Richmond, ventured to criticise the subject of hypnotism in a letter to Dr. L. G. Pedigo (*Virginia Medical Monthly*). Dr. McGuire does not think much of hypnotism, and does not believe in it at all. He contributes the following profound historical comment on the subject: "It was practised many years ago by the early Greeks, from whom, probably, Mesmer took the idea. Under different names, it has over and over again been reproduced. It comes now as hypnotism. In a year or two it will again disappear, possibly to be revived in twenty or thirty years." Dr. McGuire is, we regret to say, much behind the medical knowledge of the day, for while criticisms on the therapeutic application of hypnotism are much needed, the validity and scientific importance of hypnotic phenomena are no longer to be questioned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—At the annual meeting, October 28, 1889, the report of the Comitia Minora contained the following: *Resolved*, That the Comitia Minora recommend to the Society that hereafter members two years or more in arrears of dues shall have their names omitted from the published list of the Society, and that while thus in arrears such members shall receive no notice of the Society's meetings nor its publications. *Resolved*, That such members be notified of these resolutions, at least one month before the publication of the directory. A motion to adopt the report with its recommendation was made. Dr. Piffard objected, saying that if a physician was a member of the Society it was not legal to drop his name from the published list. Having offered an amendment to the motion, he withdrew it, and accepted one offered by Dr. Fry, to the effect that that portion of the report containing the resolutions be stricken out. Dr. A. F. Currier, a member of the Comitia Minora, stated it was not the intention to leave out the names of those in arrears of dues from the published directory, but to place them in a separate list. Dr. Laurence Johnson and Dr. Daniel Lewis spoke of the trouble and expense connected with attempts to collect back dues from delinquent members, and of the injustice of their sharing equally in most respects the benefits of membership with those who had complied fully with the by-laws. Dr. Lewis said it was impractical to do as Dr. Piffard had suggested, to collect arrears of dues through action at law. Dr. Shultz thought it would be an insult to publish a separate list of members in arrears of dues. He inquired whether the provision made for publishing the directory would not permit of including in one list only the names of members who had fully complied with the by-laws, while the names of others should appear in the general list of registered physicians. The report, including its recommendations, was adopted. Dr. Piffard wished it to appear on the minutes that he questioned the legality of the proposed procedure. Dr. John S. Warren, the treasurer, read his report, which showed receipts for the year of $4,739.95; disbursements, $3,563.90; balance in the treasury, $1,176.05. It had been found correct by the Auditing Committee, and was accepted. At the election of officers, Drs. Crampton and Currier were appointed Tellers. Dr. L. Bolton Bangs having withdrawn as candidate for the presidency, there remained but one name for each of the following offices: For *President*, Dr. A. S. Hunter; *Vice-President*, Dr. J. Leonard Corning; *Secretary*, Dr. C. H. Avery; *Assistant Secretary*, Dr. W. E. Bullard; *Treasurer*, Dr. John S. Warren. Dr. Piffard was instructed to cast an affirmative ballot for the gentlemen named, which he did. The following Censors were elected: Drs. Daniel Lewis, George H. Fox, Laurence Johnson, N. G. McMaster, George A. Abbott. Names of delegates to the Medical Society of the State of New York are as follows: Drs. D. H. Goodwillie, William Stevens, Albert S. Newcomb, Frank B. Carpenter, Samuel Lloyd, Peter A. Callan, Ralph Waldo, Urban G. Hitchcock, William A. Dayton, Charles A. Powers, Willy Meyer, Henry D. Chapin, George R. Elliott, John Dorning, Seneca D. Powell, Robert T. Morris, Francis Valk, David D. Jennings, William C. Jarvis, Malcolm McLean, Egbert H. Grandin, William P. Northrup, R. C. M. Page, Robert B. Talbot. Dr. Daniel Lewis read the report, on the "Medical Directory," and said the expenses, which had been $1,145, would be fully covered by the receipts. He requested that members send any information which they might have of change of address, etc., especially of those not members of the Society. The report was accepted, with thanks to the editor for the faithful and painstaking manner in which he had brought out the edition. By unanimous consent the by-laws were suspended, and Dr. Julius Althaus, F.R.C.P., London, and Mr. Henry Morris, F.R.C.S., London, were nominated for honorary membership. Dr. J. Leonard Corning read the report of the Board of Censors, which also included that of the counsel, Mr. Purrington, regarding the prosecution of illegal practitioners. In eleven out of thirteen cases tried, convictions were obtained. The annual dues for the ensuing year will be three dollars. Dr. Richard Van Santvoord read the report of the Committee on Hygiene, which dealt chiefly with the condition of the public, private, and parochial schools. There was still overcrowding in many districts. The new buildings, however, were better arranged, from a sanitary point of view, than the old ones. Improvements had been made in many of the latter. Superintendents and teachers in the parochial and some private schools, and in Sunday-schools, were the most derelict in complying with sanitary laws. The Secretary read the report of the Committee on Ethics, which stated that but two complaints had been made; in one the parties complained of were not members of the Society; in the other sufficient cause for action had not been shown. Dr. E. H. Grandin read the report of Committee on Prize Essays, which stated that but one essay had been offered in competition. It did not fulfil the conditions requisite in regard to originality. Dr. O. B. Douglas stated that but one essay deemed worthy of the prize had been offered in twelve years. He moved that the Comitia Minora be instructed to consider the advisability of changing the conditions on which the prize was to be awarded. Dr. J. L. Corning thought it might with advantage be awarded the member who produced the best paper during the year. The motion was carried.

A HOSPITAL FOR LIBERIA.—Liberia, the colored republic on the west coast of Africa, founded by the American Colonization Society some forty years ago, is, according to Mrs. Jane Rose Roberts, wife of the late President Roberts of the young nation, utterly destitute of institutions in which her poor and sick people can be cared for. Mrs. Roberts has come to the United States for the purpose of presenting the facts in the case to the friends of Liberia. The hospital which is needed will cost $20,000, and Mrs. Roberts has thus far in hand $1,400, with $300 promised her by the American Colonization Society. The nearest hospital to Liberia is the one at Cape Palmas, about three hundred miles from Monrovia.—*Boston Medical and Surgical Journal.*

PROPOSED MEDICAL CONGRESS IN SPAIN.—A meeting was recently held in the rooms of the Spanish Medico-chirurgical Society, at Madrid, with the view of arranging an international medical congress, to be held at Madrid in 1890. Though the proposal received influential support, the general feeling was that it would not be desirable to organize a gathering which should in any way clash with the Congress at Berlin.

# Obituary.

## PROFESSOR ISAAC E. TAYLOR, M.D.,

NEW YORK.

THE venerable Professor Isaac E. Taylor, M.D., President of the Bellevue Hospital Medical College, died suddenly at his residence in this city, October 30th. He was born in Philadelphia, April 25, 1812, and graduated from Rutgers College, N. Y., in 1830, and received his degree of M.D. from the University of Pennsylvania in 1834. In 1835 he entered into mercantile business, but returned to his profession in 1839, settling in this city. In 1840 he visited Paris and entered the office of Professor Cazeaux, and returning to this city in 1841 he commenced practice by attaching himself to several dispensaries. In 1851 he was appointed visiting physician to Bellevue Hospital, and was connected with this institution in the capacities of attending and consulting physician until his death. He originated the idea of establishing a medical college in connection with Bellevue Hospital, and carried it out. He was made the President of the college at the start, and shortly after was named President for life. He was also Professor of Obstetrics there, and lectured regularly up to about eighteen months ago. He was a very active man, and looked sharply after the affairs of the college up to the time of his death. He was consulting physician for the Bellevue, Charity, Maternity, and Woman's Hospitals, and the New York Infirmary. He was a member of the Medical Society of the County of New York, the New York Pathological Society, Physicians' Mutual Aid Association, Society for the Relief of the Widows and Orphans of Medical Men, and the New York County Medical Association.

Dr. Taylor was, during his more active career, a constant and valued contributor to medical literature, and devised numerous original operations which bear his name. His clinical experience was very large, and his counsel was eagerly sought and greatly valued, more especially in his chosen field of obstetrical work. He was married in 1835, his wife dying in 1867, leaving one son and three daughters.

# Reviews and Notices of Books.

SYNOPSIS OF HUMAN ANATOMY. By JAMES K. YOUNG, M.D., Lecturer on Orthopedic Surgery, etc., University of Pennsylvania. 12mo, pp. 393. Philadelphia and London: F. A. Davis.

THIS is a very carefully prepared compend of anatomy, and will be useful to students for college or hospital examination It is condensed to the uttermost, and is calculated more for a review manual than for the beginner. There are some excellent tables in the work, particularly the one showing the origin, course, distribution and functions of the cranial nerves.

INDEX CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, U.S.A. Vol. X. 4to, pp. 1,059. Washington: Government Printing Office. 1889.

THIS volume, which is the tenth of this remarkable series, is of the usual large size, and includes 7,658 author-titles, representing 2,905 volumes and 7,282 pamphlets. It also includes 14,265 subject-titles of separate books and pamphlets, and 29,421 titles of articles in periodicals. The compiler, John S. Billings, U.S.A., has evidently done his best to keep the present volume up to the high standard of its predecessors.

TRANSACTIONS OF THE ASSOCIATION OF AMERICAN PHYSICIANS. Third Session. Vol. III. 8vo, pp. 404. Philadelphia: Printed for the Association. 1888.

THE Association of American Physicians, although in its infancy, has already made an enviable reputation for sound and progressive scientific work. No one will fail to appreciate this fact who peruses the admirably written papers which are collected in its three volumes. The present one contains the papers read at the meeting in Washington, September, 1888. Leading with the well-timed address of the president, Dr. W. H. Draper, we have the important topics of typhoid fever, Bright's disease, and cardiac affections treated from different points of view by the members, with here and there an interesting and anomalous case. It would be unjust to the distinguished gentlemen who contribute to this volume to make any distinction as to the respective merits of papers presented. Suffice it to say that all of the topics are discussed in a very satisfactory if not masterly manner. It is a pity, however, that so much valuable material is buried practically in a volume of "Transactions," which must necessarily have a limited field of usefulness.

A TREATISE ON SURGERY, ITS PRINCIPLES AND PRACTICE. By T. HOLMES, M.A. Cantab., Consulting Surgeon to the St. George's Hospital, etc., London. Fifth Edition. By T. PICKERING PICK, Surgeon to, and Lecturer on Surgery at St. George's Hospital, etc. 8vo, pp. 1,008. Philadelphia: Lea Brothers & Co. 1889.

THIS work, which has now arrived at its fifth edition, still maintains its position as a standard text-book on the principles and practice of surgery. Not many material alterations have been made, save in the direction to add to its value. The chapter on eye diseases has been wisely omitted as unnecessary, in view of the fact that special works on ophthalmology cover this ground more effectually and satisfactorily. Among the subjects which have had more especial and extensive emendation are those on diseases of the bones and joints, abdominal surgery, and intestinal obstruction, and the operative treatment in reference to cerebral localization. Mr. Pick has performed his part of the work with rare judgment and skill. The book contains many original illustrations which add much to its merits as a whole.

TRANSACTIONS OF THE NEW YORK STATE MEDICAL ASSOCIATION FOR THE YEAR 1888. Vol. V. Edited for the Association by ALFRED LUDLOW CARROLL, M.D. 8vo, pp. 610. Concord, N. H.: Republican Press Association. New York: J. H. Vail & Co. 1889.

THE "Transactions" from this society are always interesting, practical, and instructive. For an association now but five years old it has done an amount of good work unequalled by any other in that period, and is now fairly entitled to the first rank among State societies. The methods of carrying on its discussions are novel and admirable. Certain topics are selected, and certain leading men are assigned to discuss them from different stand-points. The results have been exceedingly gratifying in giving a practical turn to the solution of leading questions which could be taken in no other way. The notable features of the present volume are the "Address on Medicine; or, Medical New York in 1800," by Dr. John Shrady; the "Address on Surgery," by Dr. W. H. Carmalt, of Connecticut; the "Introductory Remarks on Tumors," by Dr. J. W. S. Gouley, of New York, with the exhaustive discussion following the same, and also the comprehensive and practical discussion on puerperal septicæmia. In typography the book is a model of its kind.

RECTAL AND ANAL SURGERY, WITH DESCRIPTION OF THE SECRET METHODS OF THE ITINERANT SPECIALISTS. By EDMUND ANDREWS, M.D., LL.D., Professor of Clinical Surgery, Chicago Medical College, and EDWARD WYLLYS ANDREWS, A.M., M.D. Second Edition. 8vo, pp. 137. Chicago: W. T. Keener. 1889.

THE second edition of this practical work has been revised and somewhat enlarged. It is an excellent work for the general practitioner, and contains much useful and well-digested information regarding the treatment of the commoner and more troublesome affections of the rectum and anus.

## VARIOLA - SMALL POX.

From Dr. P. A. Morrow's Atlas of Venereal and Skin Diseases.

WILLIAM WOOD & COMPANY, Publishers, NEW YORK.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Vol. II. Edited by J. EWING MEARS. 8vo, pp. 225. Philadelphia: P. Blakiston, Son & Co. 1889.

THE present volume is much smaller than any of its predecessors, but is not proportionately better. It contains some excellent papers, however, among which may be mentioned "The Early Diagnosis of Malignant Growths," by Dr. J. Collins Warren, of Boston; "Hernia," by Dr. Claudius H. Mastin, of Mobile; "The Anti-tubercular Power of Iodoform," by Dr. Lewis S. Pilcher; "On Gunshot Wounds of the Intestines," by Dr. Theo. A. McGraw, of Detroit, Mich.; and "Distended Gall-bladder simulating Floating Kidney," by Dr. J. Ewing Mears, M.D., Philadelphia.

A HANDBOOK OF GENERAL PATHOLOGY. By DR. EDWIN KLEBS. Part Second. General Pathological Morphology. Pp. 836. Jena: Gustav Fischer. 1889. (*Die Allgemeine Pathologie.*)

IN none of its phases has pathology fairly recovered its equilibrium, since the powerful impetus was given to etiology by the discoveries of Koch and the formulation of a new bacteriological technique, less than a decade ago. It actually seemed for a time as if work in morphological and physiological pathology along the old lines was to be largely neglected, and the results of the older work insignificant in comparison with the new achievements which each day recorded in the fields of bacteriology. But we have learned a good deal in these few years, not only about what does, but about what does not, cause disease. We have learned that a great deal of exact and painstaking work is required to establish an etiological relationship between a given bacterium and the disease with which it is associated. And what is more to the point, we have learned that even when this etiological relationship is fully established, we have only just begun to solve the problems which a complete knowledge of its pathology demands. We are now far enough away from the glamor of the new light to be able to judge of proportion more accurately, and can now see that both the morphological and the physiological phases of pathology are rapidly advancing, although in a direction which has been considerably changed by the new bacterial discoveries and by the new technique. The older accumulations of knowledge in morphology, which are embodied largely in the works on pathological anatomy and histology, have undergone some revision in view of etiological researches, but barring the new additions, remain substantially the same. It is in general pathology that the results of recent work and discovery are most conspicuous. But general pathology is a theme which in this country secures very little special attention, either in the medical schools or among practising physicians. Falling in the colleges usually to the lot of the professor of practice, it cannot or does not, unless he be a competent pathologist, secure the attention which it intrinsically deserves. Glimpses here and there of the causes of disease and of the highly significant degenerative processes the student may indeed catch. The results of inflammations and the appearances and general phenomena of tumors he can become acquainted with in a desultory way. A knowledge of bacteriology as related to disease usually comes to him only in the most fragmentary way, and then frequently from a lecturer who, unfamiliar with its practical details and incapable therefore of deciding what are its just proportions, contents himself with an attitude not always simply of intelligent scepticism, but frequently of levity or downright hostility, or largely ignores the subject altogether. Laboratory instruction can do something, but when its practical work is done there still remains wanting, for the most part, that point of view which harmonizes and correlates the multitudes of facts and which comes from the study of general pathology. For students whose horizon is wide enough to reach beyond the limits of the final examination and the diploma, for medical men who are unfamiliar with all the bearings of the new discoveries on their previous knowledge, and for teachers who need a full exposition of our knowledge in a most intricate field, and references to the rapidly widening literature, the work of Klebs, on general pathology, will be most welcome. The first part of the work, which dealt with the causes of disease—"General Pathological Etiology, including Bacteriology"—appeared in 1887. The second part, comprising "General Pathological Morphology," and dealing at length with the degenerations, with inflammation, and with tumors, is now in our hands. This book, containing over eight hundred pages and numerous colored plates, shows like the first part, in all its details, that rich and varied practical experience, that broad and scholarly conception of his theme, and that enthusiasm for his work which those who know Professor Klebs as a writer, or personally as a teacher and investigator, would naturally expect. We must await the completion of the work by the issue of Part III., on "General Pathological Physiology," before an attempt is made to estimate its varied features in detail.

CYCLOPÆDIA OF THE DISEASES OF CHILDREN, MEDICAL AND SURGICAL. The Articles written specially for the Work by American, British, and Canadian Authors. Edited by JOHN M. KEATING, M.D. Vol. I. Illustrated. Philadelphia: J. B. Lippincott Co. 1889.

To those who have failed to keep note of the wonderful activity among the students of disease in infancy and childhood the appearance of a work such as the one before us will be a revelation. Here are four large octavo volumes, of over eight hundred pages each—the first, indeed, has very nearly one thousand pages—devoted exclusively to a study of the peculiarities of disease occurring in the young. It shows what progress medicine is making in our times, for, as Dr. Jacobi truly says in his introductory chapter, such a collection of monographs as are here presented could not have been written at the time when he began his professional life.

In a brief notice of this kind we cannot do more than indicate the contents of this first volume, any extended review of the individual articles being, of course, impossible. Even to set down the titles alone of these articles would take up much of the space allotted to notices of this sort, since there are forty-one separate monographs by nearly as many authors. The work opens with an introduction by Dr. A. Jacobi, of this city, in which are set forth the peculiarities of constitution of children, by reason of which disease occurring in them undergoes certain modifications of the type seen in the adult, and is therefore a sort of *apologia* for pædiatrics. In Part I. are considered general subjects, such as the anatomy of the child, nursery hygiene, the diseases of the fœtus, general diagnosis and therapeutics of infancy (the latter for some reason placed at the end of the volume instead of in its proper place), the pathology and hygiene of puberty, infant-feeding, etc. The Second Part is devoted to fevers and miasmatic diseases occurring in children It seems odd to read here an article on yellow fever, yet it is as justly entitled to consideration in a work of this kind as is typhoid fever or small-pox. The illustrations are numerous and of a high order of excellence.

In concluding this short notice we cannot refrain from congratulating the distinguished editor upon the happy inception of such a work as this, and we feel a measure of pride in thinking that the book is an American one. There are, it is true, several contributors from England, and their articles add not a little to the value of the book. But these are comparatively few; the editor is an American, the publishers are American, and the work itself is one which American medicine may justly claim as its own, and for which it has no cause to feel ashamed. It is at once an evidence of the progress made by students of pædiatrics in this country, and a foundation upon which these and other workers may build in the years to come. The book is valuable to every family practitioner, whose work is so largely among children and whose success in his profession will depend in great measure upon the skill with which he handles these miniature men and women.

THE LIFE REGISTER. London: West, Newman & Co. 1888.

THIS is a small book intended for recording the growth, health, etc., of children. The use of such registers is increasing, and their interest and value cannot be questioned.

LECTURES ON NERVOUS DISEASES. From the Stand point of Cerebral and Spinal Localization, and the Later Methods Employed in the Diagnosis and Treatment of these Affections. Pp. 778. By AMBROSE L. RANNEY, A.M., M.D. Philadelphia: F. A. Davis. 1888.

DR. RANNEY'S book consists of sections upon the anatomy and physiology of the nerve-centres; upon the clinical examination of patients; sections upon nervous diseases, and upon electricity in medicine, the latter section being made up chiefly of his already published treatise upon this subject.

The parts upon nervous diseases proper, and especially upon functional nervous diseases, will be found of most interest. The author entertains, as we believe, very exaggerated views as regards the influence of anomalies of the ocular muscles and of eye-strain, in producing nervous disorders. Those, however, who wish to know about and test these methods will find descriptions of the technique here. The chapter on Electricity is somewhat sanguine, but is on the whole a good one. We can hardly say as much regarding the anatomical part. The colored diagrams give picturesqueness to the pages, but the author seems at times to have sacrificed anatomical accuracy to chromatic effect. There is, however, much in this section also which will be found convenient and instructive.

SUGGESTIVE THERAPEUTICS. A Treatise on the Nature and Uses of Hypnotism. By H. BERNHEIM, M.D. Translated from the second and revised French edition, by CHRISTIAN A. HERTER, M.D. Pp. 420. New York and London: G. P. Putnam's Sons. 1889.

WE have already called attention to the work of Dr. Liebault and Professor Bernheim in the domain of mental hypnotism, and have affirmed our belief in the essential soundness of their views regarding this subject. Hypnotism has passed from the domain of empiricism and is now being made the object of careful scientific study. Its power in therapeutics is no longer questioned. Its practical usefulness and its safety as remedial measures remain still to be determined. The presentation in English of Bernheim's book will enable American readers to learn the views of scientific men who advocate the use of hypnotism by the physician, and they can themselves test and judge regarding it. We trust that no one will fail, in looking over this work, however, to read carefully the chapter on the dangers of hypnotism, which are there candidly stated. It will certainly make everyone feel that he cannot be too careful in applying it. Dr. Herter has made an excellent translation.

THE INSANE IN FOREIGN COUNTRIES. By WILLIAM P. LETCHWORTH. New York and London: G. P. Putnam's Sons. 1889.

MR. LETCHWORTH has written a most interesting book, not alone to physicians, but to all interested in the care of the insane. It contains the record of many months' careful study under most favorable conditions; and the pages are illustrated with cuts and photo-lithographs which put the volume almost on the plane of an *édition de luxe*.

A HANDBOOK OF THERAPEUTICS. By SIDNEY RINGER, M.D. Twelfth edition. Pp. 524. New York: William Wood & Co. 1889.

FEW therapeutical works are so rich in practical suggestions as this of Dr. Ringer, and no therapeutical author has been more extensively quoted or followed. Ringer's work is a classic, and its usefulness and popularity are attested by its numerous editions. A valuable feature of Dr. Ringer's work is the part devoted to general symptoms, regarded from a therapeutic point of view. The author also gives many practical hints and directions about other remedial agencies than drugs.

A TEXT-BOOK OF HUMAN PHYSIOLOGY. By AUSTIN FLINT, M.D., LL.D. With three hundred and sixteen figures in the text and two plates. Fourth edition, entirely rewritten. Pp. 872. New York: D. Appleton & Co. 1888.

AS stated on the title-page the present edition is entirely rewritten. By leaving out historical references and unnecessary discussions the work is, however, not increased in size. One new plate and sixty-one new figures have been introduced; and two plates and sixty-three figures left out.

An examination of the new work produces, on the whole, a most favorable impression. It is a good students' text-book, and no doubt will continue to merit its former well-deserved popularity.

TRAITÉ D'HYSTÉROTOMIE ET D'HYSTÉRECTOMIE PAR LA VOIE VAGINALE. Par le DR. LAURENT SECHEYRON. Précédé d'une Préface de M. PÉAN. Paris: Octave Doin. 1889.

A TREATISE ON HYSTEROTOMY AND HYSTERECTOMY BY THE VAGINAL METHOD. By DR. SECHEYRON. With a Preface by DR. PÉAN. Paris, 1889.

A STUDY of this bulky volume will strengthen an already widely accepted view, namely, that the vaginal method of extirpation of the uterus is the proper one for malignant disease of that organ. Péan does not employ sutures, using instead his well-known hæmostatic forceps to control all bleeding. The work before us contains, in the main, French statistics, and is interesting on that account to all those who wish to remain *au fait* of the special work done by the French in this branch of surgery.

SURGICAL BACTERIOLOGY. By NICHOLAS SENN, M.D., Ph.D., Professor of Principles of Surgery and Surgical Pathology, Rush Medical College, Chicago. 8vo, pp. 270. Philadelphia: Lea Brothers & Co. 1889.

THIS is a well-prepared *résumé* containing the essentials of our knowledge regarding the bacteria of surgical diseases. The compiler has selected his data with good judgment, and presents them in a clear and concise manner. As an introduction to the study of physical bacteriology the unpretentious little volume will serve a good purpose.

LEÇONS DE GYNÉCOLOGIE OPÉRATOIRE. Par VULLIET et LUTAUD. Paris: I. B. Baillière et Fils. 1889.

LESSONS IN OPERATIVE GYNECOLOGY. By DRS. VULLIET and LUTAUD. Paris, 1889.

DRS. VULLIET and LUTAUD have here collected a series of essays on many of the most important questions of modern gynecology. Several controversial matters are discussed in a spirit of fair criticism, and while no great amount of originality is displayed, the authors show that they have good judgment and a large experience. These essays will be read with interest by all who are interested in surgical gynecology.

LEÇONS DE CLINIQUE CHIRURGICALE PROFESSÉES A LA SALPÊTRIÈRE. Par O. TERRILLON. Paris: Octave Doin. 1889.

CLINICAL LECTURES ON SURGERY. Delivered at the Salpêtrière. By Professor Terrillon. Paris.

DR. TERRILLON is one of the leading surgeons of the French capital. Those who wish to familiarize themselves with the latest surgical tenets of the French school will do well to peruse those instructive class-room lectures. It will be seen from their study that modern surgery is international.

# Society Reports.

## NEW YORK ACADEMY OF MEDICINE.

*Regular Meeting, October 17, 1889.*

THE PRESIDENT, A. L. LOOMIS, M.D., IN THE CHAIR.

### GUNSHOT WOUNDS OF THE ABDOMEN, WITH SPECIAL REFERENCE TO WOUNDS OF THE INTESTINES.

DR. LEWIS A. STIMSON read the paper. It contained reference to the statistics of operative interference in cases of gunshot wounds of the abdomen prior to 1875; the cases were very few, the operation was very generally condemned, and had been performed only where there was positive evidence of intestinal perforation. Such cases dated from Boden's, in 1831. Since 1876 the cases operated upon in the Chambers Street, New York, and Roosevelt Hospitals showed a mortality of 81.2 per cent., while those not operated upon showed a mortality of sixty-five per cent. He added to the recent statistics three cases which had entered his hospital service, one of which was operated upon during his absence, by the house surgeon, and died; one of the others died, the other recovered. But no general rule could be laid down in favor of either interference or non-interference. The selection of cases in which to operate, however, was difficult. After general peritonitis or septicæmia had set in an operation would be likely only to hasten death, and reduce the percentage of recoveries from interference, and therefore should not be undertaken further than to establish drainage. When the ball had entered the abdominal cavity it was almost sure to have perforated some of the viscera, particularly if its direction were not oblique.

He offered objections to rectal injection of hydrogen gas for diagnostic purposes, pronouncing it distinctly inferior to exploratory incision in facility, efficiency, and security.

DR. JOHN A. WYETH thought the question of whether to operate or not was in almost as much doubt, notwithstanding further statistics, as it was nine years ago when Dr. Sims read a paper on the subject. He quoted the conclusions contained in that paper, as they appeared in THE MEDICAL RECORD, October 5, 1881, as expressing his views to-day. There could be no fixed rules regarding interference and non-interference; the surgeon would have to be guided by the condition of the patient, situation of the wound, direction and size of the missile. When the opening was small, the mucous membrane of the intestine might pout and prevent extravasation. After extravasation and the development of peritonitis the establishment of drainage was all that could be hoped for from operative interference.

DR. ROBERT ABBE had seen large perforations made by bullets of twenty-two calibre. Extravasation was less likely to take place if the perforation was near the mesenteric attachment than if on the other side, as he had observed in one case. If the patient were seen in time, an exploratory operation should be made. The absence of blood from the urine was not proof that the bladder or kidneys had not been injured. Immediate anastomosis should not be advocated, since to prolong the operation even some minutes might be the cause of a fatal termination. He also condemned injections of hydrogen gas for diagnostic purposes.

DR. WILLY MEYER had operated on a man who had a bullet-wound of the abdominal walls anteriorly. The bullet could be felt near the spinal column; he had hæmoptysis, and had also once vomited blood from the stomach. Yet at the operation the outer wall of the stomach near the cardia was found only to have been scratched by the bullet, the mucous membrane not being divided. The patient died after about fourteen hours, but no autopsy was obtained. In Vienna a patient was shot in the abdomen, did not vomit blood, recovered, had hæmatemesis after six months, died, and at the autopsy it was found that the bullet had passed through the stomach, making two perforations, which had healed but reopened, causing the hemorrhage. Dr. Meyer thought the technique of this form of abdominal surgery would improve, and that it would be safer for the patient to have the abdomen opened than left alone.

DR. B. F. CURTIS thought the statistics contained in the paper were unreliable, as being unfairly prejudicial to operative interference by able surgeons. They might make a better showing if the cases of bad operators could be ruled out. He was glad to see the operation when practised upon moribund patients condemned. Here drainage would effect all that could be hoped for.

DR. THOMAS MANLEY mentioned some points in a case which he saved by operation, and reported two years ago. More recently he had seen two other cases in which it was known that the lower part of the lungs was penetrated, but it was not positive that the stomach had been touched. One man recovered without an operation, the other died shortly from internal hemorrhage. Operative interference should not be delayed, not even on account of shock.

DR. STIMSON closed the discussion, and said one could not be guided by the size of the bullet in deciding whether to operate or not. Replying to Dr. Curtis, he said one operator could give one hundred as his percentage of recoveries, but he had had only one case.

Collective experience in these cases might be of advantage in determining when to operate, but improvement in technique would have to come from experience in general surgery.

### A PORTRAIT OF DR. HOWARD PINCKNEY

was presented by the family, and was accepted by the Academy with a vote of thanks to the donors.

## SECTION ON SURGERY.

*Stated Meeting, October 14, 1889.*

ROBERT ABBE, M.D., CHAIRMAN.

### PRESENTATION OF CASES.

DR. F. B. CURTIS presented a case of

### SUTURE OF THE DIVIDED FLEXOR TENDONS OF THE HANDS.

A young man, a year ago last July, sustained a wound of the left forearm by glass, dividing all the flexor tendons. The tendons were sutured immediately after the accident, and all healed by first intention excepting one, which sloughed and healed by granulation. A depression was left at the place of sloughing. The patient afterward had considerable power in the flexors, which had continued to increase, yet Dr. Curtis thought his condition might be improved by freeing the tendons from the cicatricial tissue which surrounded them.

THE CHAIRMAN thought the question of further repair was one of a great deal of interest. He saw no reason why the tendons might not be isolated where they were bound down by cicatricial tissue and allowed to take their place after separation in new cellular tissue, which would permit of free use.

DR. REGINALD SAYRE called attention to the case presented by Dr. A. M. Phelps last spring, in which a cut across the forearm had divided all the flexor tendons and these had united in a mass. Dr. Phelps afterward dissected them out, separated them, and allowed union to take place under blood-clot. He understood the result had been good.

DR. A. M. PHELPS said that motion in the hand in that case had been somewhat improved, but the result had not been as good as he had expected, and not as good as it had been in two other similar cases. He thought the man had used the hand a little too much; the result would have been better, he believed, had it been kept in the splint in the extended position five or six weeks, permitting of a little active motion once perhaps in two or three days.

EXCISION OF TUBERCULAR BODIES IN THE SHEATHS OF THE FLEXORS OF THE THUMB AND INDEX AND LITTLE FINGERS.

THE CHAIRMAN presented a woman on whom he had excised the sheath of the flexors of the thumb and index and little fingers because of the growth of melon-seed bodies, now recognized to be the result of tubercular inflammation. The case was interesting in connection with the question of secondary operations to free divided tendons. Notwithstanding complete removal of the sheath of the tendons in this case, and in other cases, freedom and power of motion had afterward been complete. The wound, of course, must be kept antiseptic, and primary union take place, without any pus. In his case only voluntary motion was resorted to; this was begun on the sixth day.

DR. CURTIS related the case of a girl who, last winter, had suffered from an attack of cellulitis in the hand. When he saw her she had entirely recovered, but the right forefinger was bound down by adhesions in the tendon at the metacarpo-phalangal joint. He laid back a flap, found the tendon and its sheath bound together in a mass of fibrous tissue, dissected them apart, put the finger in extension, closed the wound, kept up active motion, and had a result of normal power and motion.

HEALING UNDER BLOOD-CLOT FOLLOWING PARTIAL EXCISION OF BONES OF THE ANKLE.

DR. A. M. PHELPS presented a boy, about seven years of age, who had been submitted to excision of the astragalus for tubercular disease of the ankle-joint. The disease relapsed, other bones becoming involved, and a surgeon had condemned the case for amputation. The patient then came under Dr. Phelps' care, and he opened the joint, followed sinuses down to the bones, and scraped nearly all the bone out of the periosteal covering except in the cuneiform. After suitable dressing without ligation of the vessels, the Esmarch bandage was taken off and the cavities allowed to fill with blood. The dressing was not changed for three weeks; union was primary; at the end of five weeks the bones had become solid, there having been reproduction of the os calcis, cuboid, and scaphoid. There was very good motion of the ankle-joint, the child walking as well as he had ever done. The operation was done last May. A plaster-of-Paris dressing was worn some time after the fifth week.

EXSECTION OF THE ANCHYLOSED KNEE; UNION BY BLOOD-CLOT.

Dr. Phelps also presented an Italian girl who, when five years of age, had had extensive osteo-myelitis, involving apparently the entire tibia, fibula, and femur. The knee was anchylosed at a right angle. The patient had lain in bed five years. The question was debated whether to amputate or to exsect the knee. The latter method was adopted in November last, and it was Dr. Phelps' intention on cutting down upon the knee to perform Fenwick's operation, making the end of one bone concave and the other convex, but he found tubercular or fatty degeneration in the interior of the femur and tibia, and consequently scraped them out, leaving only the shell, which he coaptated in a straight line by wires, allowing the cavities to fill with blood. When the first dressing was changed, at the end of five weeks, the clots had organized and formed bony union.

DR. POWERS inquired of Dr. Phelps what histological changes took place in the reproduction of bone through blood-clot.

DR. PHELPS replied that the blood-clot itself was not supposed to organize, but that it acted as a framework for the growth of the cell-tissue which took place in it, constituting the normal elements in that particular locality. As the new tissue formed the blood-clot became absorbed.

DR. B. F. CURTIS read a paper (see p. 449) on

KNOTS, LIGATURES, AND SUTURES.

THE CHAIRMAN thought the paper showed in modern surgery a weeding-out process as regarded numerous methods formerly employed to accomplish the same objects. He thought this might be carried a little farther by dropping the hare-lip pin and excluding from the list of operations lumbar colotomy, its place being taken by inguinal colotomy. He had noticed that some operators, in tying a ligature around a bit of a bleeding vessel, dropped the forceps before making the second knot. He thought this was no more convenient than to leave the clamp on until the knot had been completed, and was somewhat unsafe, inasmuch as a bit of tissue dropped by the forceps might enter between the knots. In certain cases, as in wounds about the face, it was sometimes desirable to stuff the wound with iodoform gauze, take it out after twenty-four or forty-eight hours, and insert sutures. He had learned by experience to avoid giving the patient pain, if an anæsthetic was not given, by introducing the sutures at the time of the operation, and tightening them at the second dressing. The wound was sticky, and primary union took place with as narrow a cicatrix as usually took place when the sutures were tied in the first instance.

DR. REGINALD SAYRE believed the buried shoemaker's stitch had not been mentioned. It was very desirable in certain plastic operations.

DR. DAWBARN called attention to a way of obviating the tendency to a fold at the end of the continued suture, namely, by threading the needle at both ends and beginning in the middle of the wound. He also said that the surgical knot was not so likely to loosen before being tied the second time if the first portion were jammed in the angle of the wound by a sudden half-twist of the two suture ends. In gastrotomy it was surprising to observe how rapidly union took place by scratching the opposing peritoneal surfaces. He had recently used Abbe's catgut rings in a case of enterotomy, and although the patient died of shock, yet the rings were readily applied and gave great satisfaction.

THE CHAIRMAN having spoken of an apparent fracture at the end of a finger, consisting, probably, in rupture of the extensor tendon, which in one case he cut down upon and sutured, Dr. Gibney said he had seen similar cases, and had had opportunity in one to test hyperextension kept up long enough to cure the case. The Chairman thought Dr. Gibney's method, where it could be carried out, was preferable to suturing. Dr. Van Arsdale had cured one such case by a splint.

DR. A. J. MCCOSH read a paper giving a

REPORT OF A CASE OF NEPHRO-LITHOTOMY FOLLOWED BY NEPHRECTOMY.

The symptoms pointing to renal calculus had existed three years or longer, which various kinds of treatment had failed to relieve, until in July last he cut down through the lumbar muscles, and removed through kidney tissue proper a calculus which was felt in the pelvis of the organ. The stone weighed one hundred and twenty-two grains. The kidney was apparently little diseased, and no pus escaped. Two sutures were placed in the capsule, drawing the incision together. Pain ceased; the urine for a while contained blood; after a few days some pus escaped through the dressings, but at the end of three weeks the patient got out of bed, and was considered well, except for the granulating sinus in the loin. On the afternoon of the thirtieth day from the operation the patient complained of pain in the region of the kidney; passed some blood in the urine; the pulse increased. The symptoms continued next day; the sinus in the loin was broken up. The symptoms growing worse, the finger was pushed down, it was supposed, upon the kidney, reopening it apparently, for urine and blood discharged. The hemorrhage was controlled by iodoform gauze. The urine containing pus, on the fourth day the packing was removed, and it was

thought the hemorrhage from the wound would not recur, but it proved more profuse than on the previous day. It continued after the dressing, as indicated by the urine, and the next day, the thirty-fifth after the primary operation, it was determined to cut down and freely expose the kidney. The last rib had to be excised to permit of drawing the kidney well up into the wound. It was removed. It contained another small calculus. The edges of the previous wound were sloughing, and the whole organ was congested. Some hours after this operation there was complete suppression of urine, and the patient died within thirty-two hours in a state of coma. Dr. McCosh thought it probable that the nephrectomy would not have proven more successful had it been done on the afternoon of the thirtieth day.

## THE PRACTITIONERS' SOCIETY OF NEW YORK.

*Stated Meeting, October 4, 1889.*

V. P. GIBNEY, M.D., PRESIDENT PRO TEM.

DR. V. P. GIBNEY read a communication (see p. 482) entitled,

### THE MECHANICAL TREATMENT OF DROP-WRIST AND ALLIED PARALYSIS.

DR. DANA said that the apparatus, if really of the value apparently shown, would be a most valuable addition to the therapeutics of this disease. In his experience wrist-drop from lead and pressure was the common form of the peripheral paralyses, among the working-classes at least, and it was sometimes very intractable to treatment. The history of Dr. Gibney's case seemed to show that the apparatus was of positive value.

DR. G. F. PEABODY, while ready to admit clinical demonstration of the value of the treatment, could hardly understand how the splint could secure such results by simple immobilization.

DR. GIBNEY thought that the modus operandi was by the entire rest it gave to the muscle.

DR. BRYANT thought the interesting question was whether rest of the wrist would cause recovery more quickly than if it were allowed to be exercised. The natural view was that in a case of paralysis of the muscles a certain amount of exercise promoted their recovery.

DR. GIBNEY also reported a case of

### SUPPURATIVE OSTEITIS OF THE KNEE-JOINT.

The patient I present this evening is one who was left me as a legacy in the Hospital for the Ruptured and Crippled in November, 1887. The boy had been for many years an inmate of the hospital, under treatment for hip disease. The active disease had long since expended itself, and there remained a high degree of deformity of the left hip, which I proceeded to treat by manual force under ether at different sittings, and finally employed the protection hip-splint which he now wears. The history of the right knee dates from September, 1888. The cause of the invasion of disease here has not been discovered. The substance of the notes taken from the hospital record is as follows:

September 8, 1888.—For the past week has complained of pain about the right knee, and for the past two days the pain has been very severe. The right knee is sharply flexed, and there is much reflex spasm. The hip functions are found to be perfect, but the normal contour of the knee has changed somewhat. There is no evidence of synovial distention, but there is considerable tenderness over the inner head of the tibia. A diagnosis of osteitis is made, and the knee is put up in plaster-of-Paris.

September 13th.—Knee found greatly swollen from distention of fluid, patella cannot be made to touch the inner condyloid space; has some cellulitis on the inner aspect of the knee. An aspiration into the joint relieves him of nearly two ounces of thickish serum.

On September 15th an incision made over the head of the tibia into an abscess, with evacuation of about an ounce of pus.

September 20th.—Has obtained some relief, but the sinus is still open.

By October 1st discharge was very profuse, boy suffering very much, and a bracketed splint is applied in order that the knee can be the better dressed.

October 5th.—His suffering has been very great. The synovial sac is much distended. The tenderness and soreness over the head of the tibia is such that no local applications give any relief. Under ether to-day an incision one and one-fourth inch in length is made over the inner head of the tibia, right side, and the bone in this locality is found to be quite extensively softened, the tissue being broken down so that the finger can be inserted well into the head. The parts are thoroughly scraped with a Volkmann's spoon, and all necrotic tissue thoroughly removed. The cavity is about one and one-half inch in depth. There was very little hemorrhage. Before completing the operation the whole cavity is cauterized with the tip of the Paquelin cautery, and after washing out with sublimate solution, is packed with iodoformized gauze, and dressed antiseptically throughout. The joint-cavity is not invaded by the operation, but a large needle of an aspirator is introduced, when about two ounces of serum is withdrawn containing a number of flocculi. The sac is then washed out with carbolic acid, 1 to 40, and the limb put up in a plaster-of-Paris bandage.

October 7th.—Patient is doing well, gauze is removed and found to contain very little discharge. Temperature yesterday evening was 101½° F.

November 7th.—His improvement has been uninterrupted, he has gained flesh, his intellect, which, by the way, was apparently much impaired before the operation, has become clearer. The special impairment of intellect was a moroseness, peevishness, with some muttering occasionally, which made us very anxious about the mental condition.

On December 5, 1888, the plaster-of-Paris is removed. Knee found in excellent condition, motion over an arc of from 15 to 20 degrees; no joint effusion; wound healed, no sinuses. From this time until March 16th there was nothing of special importance. We kept him in a wheeled chair for a long time, gradually left off all dressings from the limb, and on March 20th he was discharged with function of knee about perfect, able to walk about, and had not complained of any pain or inconvenience for two or three months. He was provided with a canvas knee-lacing as protection, and has been attending occasionally the out-patient department to have his hip-splint attended to.

October 2d.—I saw him in the out-patient department to-day and found his knee still in excellent condition, and it is as you see it this evening. His range of motion seems to be perfect, there is no synovitis present, and the cure is complete.

DR. BRYANT said he had only seen three cases where the knee-joint was implicated indirectly.

DR. SHRADY stated that, in cases of abscess of the head of the tibia, it was almost astonishing to know how closely the cartilage of incrustation could be invaded in an operation without extension of trouble to the knee-joint. In two cases which he had operated upon recently the partition was exceedingly thin, but no trouble followed the operation. In the majority of cases of extension of inflammatory processes which had come under his observation the route of involvement of the joint was more or less indirect, by burrowing underneath the cartilage, and around and through the ligamentous tissues surrounding the joint.

DR. JOSEPH D. BRYANT presented specimens removed in a case of

### STRANGULATED HERNIA.

The specimens presented were the omentum, which had been removed previously from an old and recently stran-

gulated entero-epiplocele, together with the sac, which was ligatured, cut off, and the wound treated by the open method for radical cure. The specimens were intended to illustrate the evil effects following persistent, continuous, and forcible taxis for forty minutes or so, with the patient under the effects of an anæsthetic. The omental contents, together with the sac, were inflamed to a degree giving rise to a capillary oozing from the newly formed vascularity of the continuous surfaces of the sac and its contents. Only the superficial layers (integument and two layers of superficial fasciæ) had escaped recent agglutination with the remaining agglutinated coverings of the hernial protrusion. Twenty-four hours after the taxis the patient's temperature had risen to 101½° F.; pulse, 96; the contiguous tissues were swollen, œdematous, tender, and somewhat painful. The operation for the open method of treatment was performed. At the end of four days the condition of the tissues was such, as the result of the vigorous taxis, that any other than the open method of treatment was deemed to be inexpedient, if not unsafe.

Dr. Shrady said that patients generally had a better chance when the operation was done at once than to trust to taxis, as ordinarily done by the general practitioner. He had seen more damage from injudicious resort to taxis than from any other source. He thought it ought to be the rule that if a well-qualified man cannot succeed in reducing the hernia under ether, the operation should be done before the patient was allowed to wake up. In other words, never attempt taxis, under ether, unless everything is prepared for an immediate operation.

Dr. Robinson inquired with regard to the old method of applying a rubber bandage in such cases.

Dr. Bryant said that in an irreducible hernia the rubber bandage might answer, but in strangulated hernia it would not.

Dr. Dana read a paper (see p. 478) entitled

ELECTRICAL INJURIES, WITH REPORTS OF SOME CASES.

Dr. Bryant said that he had only seen one case, and that, he thought, was one which Dr. Dana had already reported. The man suffered very severe surgical injuries of the hand, and the hand finally had to be amputated.

Dr. Herman M. Biggs said that, through the courtesy of the coroners' physicians, he had been invited to view the bodies of five persons who had been killed by shocks from the electric-light wires. In four of these autopsies had been performed.

The first case was that of a boy aged fifteen years who was killed in April, 1888. While passing along the street he grasped a broken telegraph wire which hung from an electric-light wire. He instantly fell to the ground with some convulsive movements, and when persons who saw him fall reached him he was dead. In this case there were no superficial burns. The accident occurred on a wet morning, just after a severe rain.

In April, 1888, a few days after the accident in the previous case occurred, a clerk grasped the support of a low hanging electric light on the Bowery, while he was standing on some iron doors leading to the cellar. He fell with some convulsive movement to the ground, dead. In this case there were some extensive burns of the thumb and index and middle fingers of the right hand. This accident also occurred on a wet day.

In May, 1888, a lineman while repairing wires on the second floor of a building on Murray street, lost his balance and grasped a supposed dead wire and was instantly killed. There were extensive burns of the hand and also burns over both knees, about two and a half inches in diameter. He was kneeling at the time of the accident on an iron window-casing. His trousers and drawers were burned through at the knees where they rested on the iron casing.

In the early part of the present year an engineer was found lying on the floor, dead, near a dynamo in the engine-house of one of the electric-light companies. There were no external injuries found on the body.

In September, 1889, the superintendent of an electric-light plant was killed instantly by coming in contact with an electric-light wire. There were severe burns found on the hands and on one arm in this case.

Autopsies were performed in the first four cases detailed above, and with the exception of the fourth case, in which no lesions of any kind were found, the changes in the viscera were practically the same and were briefly as follows: The blood was dark and fluid everywhere, the viscera were congested, especially the lungs, and there were petechial hemorrhages in the pleura, pericardium, and peritoneum. In one or two of the cases there were also some larger hemorrhages underneath the pleura. On many of the points of hemorrhage in the serous membranes there were delicate deposits of fibrin on the surface of the membrane.

Rigor mortis was well marked in all the cases.

Microscopical examination of the organs was not made, but examination of the blood did not reveal any morphological changes in the corpuscles.

Dr. Frederick Peterson stated that he did not believe any new or unknown disease had been introduced by the employment of dangerous electrical currents in various industries, for precisely the same disorders have been known to the profession as occurring from electricity in its natural form of lightning. Lightning produces shock of all degrees to the nervous system. As one-third of the people struck escape death, it is from disorders of the nervous system that these victims suffer, and these disorders are commonly functional in character. Among the most frequent neuroses, generally of a transient character, produced by lightning, are catalepsy, aphonia, deafness, blindness, tinnitis aurium, neuralgias, iridoplegia, and various paralyses and anæsthesias. One instance was that of an intermittent brachial monoplegia recurring at every storm. He cited the experiments with artificial lightning—discharges from Leyden jars—made upon lower animals by Richardson twenty years ago, and by Nothnagel nine years ago, in which varying degrees of anæsthesia and paralysis were produced, transitory in nature.

As to the pathology of electrothanasia, he had made autopsies upon a number of dogs at the Edison laboratory, after killing them with dynamo currents, and examined many tissues microscopically immediately after death, and some later, after hardening in Müller's fluid. In all the blood was dark and thin. Electricity has been shown experimentally to rob the blood of its oxygen; a shock sent through a test-tube of blood will darken it, while shaking in a jar of oxygen restores the redness. The blood and all the visceral tissues seemed normal under high magnification. He had examined microscopically lung, muscle, nerves, spinal cord, brain, etc., but found no changes. In two dogs there were capillary ectasies in the sheaths of the large leg-nerves through which the current had passed, and also in the spinal cord, with here and there extravasations of blood. The action of the current is probably both chemical and mechanical. Its mechanical force is expansive or explosive in its nature, thus accounting for the coarse lesions found often after death by lightning—perforation, amputation, etc. The following case had been referred to Dr. Birdsall and himself by Dr. M. D. Field for examination, and was a good example of the sort of neurosis produced by a shock from a commercial current.

August J——, aged twenty-five, Elevated Railroad employee, hitherto a very strong and healthy man, on August 13, 1889, about 11 A.M., while at work picked up a wire on the Elevated Railroad, which was probably dead, but enlivened by his moving it and bringing it into circuit with some other. He had a buzzing in his head, and instant muscular rigidity followed almost immediately by relaxation. He had evidently made a circuit by picking up the wire, and his tetanic spasm had broken it again. He felt momentarily unhurt, then fell in a heap and was conveyed

to hospital. In the ambulance he recovered consciousness, but was so drowsy at the hospital that they forcibly kept him awake. He was burned but very slightly. He was able to walk home unassisted at 6 P.M. the same day. For a week he had considerable muscular twitching, like chorea; suffered from insomnia, and when asleep would dream of touching the wire, getting a shock, and would then suddenly waken. There is no sign now of any organic disease about him. He is unable to work, however. He has pain in moving his eyes, but his eyes are normal. He walks in a stooping position, and says he cannot straighten up because of pain in his back. His muscles twitch occasionally, according to his account, and he has a slight tremor, and the knee jerks and wrist-jerks are exaggerated. He is troubled with headache, and his face has a somewnat anxious look. He evidently has sustained a profound shock to his nervous system, and his mind is much absorbed in the contemplation of his morbid condition and symptoms. His state is more than one of neurasthenia, and less than hypochondriasis. It evidently corresponds to the traumatic neuroses due to other kinds of shock, like railway-brain, railway-spine, etc.

He mentioned another case of a man in whom choreiform movements had developed after a severe shock from an electric-light wire.

DR. PEABODY reported a case of

HEMORRHAGE IN THE MIDDLE EAR IN FRACTURE OF THE BASE OF THE SKULL WITHOUT EXTERNAL SIGNS OF HEMORRHAGE.

The case which I have to narrate this evening relates to a fracture of the base of the skull, the line of fracture having passed through the petrous portion of the right temporal bone.

The patient presented none of the usual symptoms, such as hemorrhages and motor paralysis or spasm, and the diagnosis was rendered certain only by the use of the ear-speculum.

The patient, W. H.——, thirty-seven years of age, married, a native of the United States, was driver of a sweeping-machine by occupation.

He was admitted to Bellevue Hospital on September 25, 1889. He stated that the previous night, at midnight, while at work upon his machine, he became suddenly dizzy and fell to the ground, without, however, sustaining any severe injury or contusion. When he got up he was still dizzy and was suffering from a very severe pain in the head which was especially marked in the right parietal and occipital regions. It was of such severity as to prevent him from sleeping during the rest of the night. It had also prevented him from working or even attempting to work. When he was admitted to the hospital, late in the afternoon of the day following the injury, he complained of an exceedingly severe pain in his head, located where I have described it, and he was very deaf. He could be made to hear only by shouting very loudly in close proximity to him.

The house physician gave him the usual dose of antipyrine, and had him put to bed at once.

I saw him the following afternoon and found him suffering exactly as he had been when he entered the hospital. His tongue was heavily coated, his breath foul, and his bowels very constipated. He was still sure that he had sustained no violence in his fall; even in response to close questioning it could not be ascertained from him that his head had come into contact with anything harder than the brush of his sweeping-machine.

I ordered him a dose of calomel to move his bowels, and directed that fifteen grains of phenacetine be given for his headache.

The next day his bowels had moved, but his headache and deafness were unchanged.

As it had occurred to me several times in the autopsy room to find, in fractures of the petrous portion of the temporal which had given no evidence of their presence by bleeding upon the surface of the body, that there nevertheless had been hemorrhage into the middle ear sufficient to surround the ossicles with a clot of blood, I determined to use the ear-speculum in this case.

It is, of course, plain that to get bleeding from the ear in fracture of the skull we must have the fracture, with hemorrhage into the middle ear, *plus* a laceration of the membrana tympani. If the latter factor be not present, and the blood not sufficiently abundant to escape through the Eustrachian tube, it will remain shut up in the middle ear. I had seen this condition in several instances where the diagnosis had not been made until it was disclosed by the autopsy.

The use of the ear-speculum in this patient showed a small hemorrhage in the periphery of the membrana tympani arteriorly, and elsewhere in the periphery there was visible an abundance of venous blood on the inner aspect of the membrane. In the left ear the membrane was found to be thickened and white, presenting the appearance of pathological alterations of old date.

I at once had the man removed to the quietest corner of the ward, and put him upon large doses of sodium bromide.

On the same day he was visited by his companion in the street-sweeping work. This man said that the patient's tale was very different from the facts: that he had fallen to the ground with great violence, and had struck his head very forcibly against some of the iron of his sweeping-machine in front of the revolving brush, that he was entirely unconscious when he was lifted from the ground and had remained so for a considerable time, less than an hour, and that he was dazed and stupid and very difficult to arouse during the following night and day preceding his entrance to the hospital, and that he complained of nausea, and had vomited soon after the accident.

His subsequent history is very brief. He remained in the same condition as to pain in the head and deafness for nearly a week, although he was kept somewhat dull and stupid by full doses of the bromide. After this time the pain began to disappear, and with it his deafness rapidly improved. Two weeks after the accident the pain had disappeared entirely, but the deafness still continued quite marked, although much less so than it had been at first. The blood was still visible through the membrana tympani. At the date of preparation of this report of his case, one week after the meeting of the Society, he was so much improved that he insisted upon leaving the hospital and going to work, in spite of my advice to the contrary.

It seemed to me that the case was of some medico-chirurgical interest in view of the difficulties in the way of a positive diagnosis in such cases, and also in view of the very great importance of making the diagnosis as the only safe basis of prognosis and treatment in a condition which is always grave.

Dr. Peabody said, in reply to a question as to the degree of deafness, that it was very considerable; he could only converse with the patient by shouting.

DR. SEXTON thought that no very great deafness could arise from hemorrhage in the middle ear. He thought that the injury must have involved central parts other than the middle ear in order to cause a great degree of deafness.

DR. WALKER said that he had met with a case which resembled that of Dr. Peabody's, several years ago. He was called one day to see a boy, aged six or seven, who had fallen off from a high stoop, where he was playing with some other boys. He had struck on the back of his head, and was somewhat stunned. He had some cerebral symptoms, vomiting, and feeble pulse, so that he was led to examine for injury of the skull. He found the middle ear filled with blood, as shown by the congestion, and appearance of the tympanic membrane. It remained filled with blood for a period of fourteen days. Dr. Roosa saw him afterward. Finally he recovered. He had no external bleeding, no hemorrhage into the eye, into the orbital or nasal cavities, and the diagnosis of fracture of the base was made on the finding of blood in the middle ear.

Dr. Sexton said that, in rare cases, where there was thickening of the membrane of the drum, it would be pretty hard to tell whether there was blood in the middle ear. He thought it would sometimes be difficult to tell the presence of extravasations from some tumor that had existed there.

---

## AMERICAN PUBLIC HEALTH ASSOCIATION.

*Seventeenth Annual Meeting, held at Brooklyn, N. Y., October 22, 23, 24, and 25, 1889.*

(Continued from p. 468.)

### Third Day, Thursday, October 24th—Morning Session.

President Johnson, of Chicago, took the chair at 9 A.M., and some business matters were attended to.

Dr. John S. Billings, U.S.A., discussed the paper on "The Prevention of Phthisis Pulmonalis," read on the preceding day. He argued in favor of the belief that the sputa of consumptive patients is the essential factor in communicating the disease. Not more than one case in ten thousand receives the infection through the breath. Greater precautions should be taken in the disposal of the expectorations of phthisical patients.

Dr. Albert M. Gihon, U.S.N., recommended the adoption of a resolution stating the sense of the Association to be that the destruction of the sputa is necessary to limit the spread of this disease.

Dr. R. Martin, Commissioner of Health, Milwaukee, Wis., read a paper on

#### THE DISPOSAL OF GARBAGE AT MILWAUKEE.

The subject of the various cremators was discussed, and those now in the market condemned as unsatisfactory and useless. Cremation as a system has had its day. Its claims have been exaggerated, and speculations given as facts. The cremator used in Milwaukee for twenty months, doing the entire work of the city, was found to be objectionable. The system now in use there is the Merz System, which gives satisfaction. It has been used constantly since June 11th. The quantity of garbage daily collected and disposed of is now fifty tons. The collecting carts drive up a covered roadway to the second story of the building, and the garbage is thrown on the floor and scraped into driers. Eight to eleven hours are spent in drying and eight hours more in the extractors, where the oily matter is removed by benzine. When the bones are separated the process is complete, and a good fertilizer is the result. There is no odor about the building save in the room where the garbage is deposited, and there very slight.

Dr. S. S. Kilvington, Commissioner of Health, Minneapolis, Minn., followed with a paper giving

#### STATISTICS ON RIVER POLLUTION, WITH OBSERVATIONS RELATING TO THE DESTRUCTION OF GARBAGE AND REFUSE MATTER.

In the majority of cities the problem of the disposal of waste matter is practically unsolved. A circular letter was sent to health-officers in one hundred and seventy-five cities in the United States, and replies were returned by only sixty-six. Less than one-third of these showed the possession of any statistics regarding the quantity of waste materials disposed of per annum. A surprising indifference to the subject is shown in many directions. Health-officials in cities of one hundred thousand to five hundred thousand inhabitants "have not thought about it," or "have no opinion on the subject," or "have had no experience and entertain no views." We can no longer leave to nature the chemistry of our waste products without danger to ourselves. The practice of pollution of water-courses by the deposit therein of waste material is undesirable at best, and intolerable where rivers or lakes are used as sources of water-supply. In the Mississippi River, during the past year, eight cities alone deposited 152,675 tons of garbage and offal, 108,250 tons of night-soil, and 3,765 dead animals.

In the Ohio River, five cities in the same period dumped 46,700 tons of garbage, 21,157 tons of night-soil, and 5,100 dead animals. In the Missouri River, four cities cast 36,100 tons of garbage, 22,400 tons of night-soil, and 31,600 dead animals. No theory of self-purification of running water will serve to dwarf the magnitude of this sanitary crime. Earth-burial of waste materials in large quantities within or near large cities should also be condemned. Two methods remain which commend themselves to students of this matter.

1. Rapid decomposition of waste products by speedy withdrawal of the water and gases contained, with a view to converting them into profitable forms of fertilizer and machine oil.

2. Rapid and complete combustion, with a view to their entire destruction.

Rendering works have attempted the production of fertilizer by the former method. A scientific apparatus, known as the Merz System, is in operation in three or four cities. It is not yet proven to be a sanitary or economical solution of the problem. Cremation is the better way of destroying combustible materials, and sewage and night-soil should be deodorized, diluted, and used as a fertilizing agent. This method has been proved a practical success in many large cities. There were twenty-three, out of thirty-five health-officials written to, who indorsed the cremation system. Household cremation of animal and vegetable waste, by kitchen ranges and furnaces, is an economic and sanitary possibility.

Dr. G. C. Ashmun, of Cleveland, O., presented a resolution instructing the Executive Committee to secure, for the next meeting of the Association, a presentation of the causes and means for prevention of diphtheria. Another resolution requested the same committee to prepare a plan for uniform classification of vital statistics.

Professor W. O. Atwater, Director of Office of Experiment Stations, Department of Agriculture, Washington, made an address on

#### FOOD IN ITS RELATION TO HEALTH.

Charts were shown illustrating the nutritive value of different dietaries, and comparing the quantities of food consumed by various classes of people in the United States and Europe. Great injury results in this country from overeating, particularly of meats and sweetmeats. The standard of German physiologists is exceeded by nearly all classes here. Sedentary persons consume as much food as would be required for active muscular work. The system is taxed in excretion of the excess of food, and thus undermined and predisposed to disease.

#### DISCUSSION.

Dr. Jerome Walker thought that we all eat more than necessary, and gave some facts from the experience in his own family. He claimed that meat once a day was enough for any ordinary person. The practice of children consuming large amounts of crackers was condemned.

Edward Atkinson, of Boston, had gathered facts to show the size of the American man, by inquiries of dealers in ready-made clothing. From measurements of about two hundred million garments he learned that the average man is 5 feet 9 inches in height, measures 34 inches around the waist, and 36 inches, chest, and weighs between one hundred and fifty-five and one hundred and sixty pounds. In a similar way he learned that the Southerner had gained one and a half inch in waist-measurement since the war.

With regard to the disposal of refuse, Dr. Edward Clark, Health Officer of Buffalo, N. Y., spoke in favor of the extractive method, and said the Merz System had given great satisfaction in his city, where the method was first tried. Health-officers from numerous cities had inspected the works and approved them. A heat of 350° F. is obtained in the driers, and all disease-producing

germs are destroyed. Night-soil and sewage are not treated by the works in Buffalo.

MR. HENRY A. FLEISCHMAN, of Milwaukee, spoke of the economic side of the question. The larger the amount of garbage the greater the saving to the city by the Merz System. It has been adopted in eight cities, in some of which cremation had been tried and abandoned. The latter method may be sanitary but is wasteful. It is found by extraction that fifty-five per cent. of garbage is moisture and ten per cent. grease; the remaining thirty-five per cent is a useful fertilizer.

Drs. McDonald, of Missouri, Conn, of New Hampshire, Van Derbergh, of Buffalo, N. Y., Clough, of Denver, Col., and Gihon, of U. S. Navy, also discussed the subject.

DR. H. W. WELLS, Medical Inspector of the U. S. Army, called the attention of the Association to the Washington

MUSEUM OF HYGIENE.

He made brief mention of its history and work and invited inspection by the members willing to visit it.

The meeting adjourned, to meet at the Hoagland Laboratory of the Long Island Medical College in the afternoon.

---

AFTERNOON SESSION.

DR. E. PLAYTER, of Ottawa, Canada, read a paper on the

PREVENTION OF TUBERCULOSIS IN MAN.

Among the predisposing and preventable causes of pulmonary tuberculosis, the most marked are: First, malformation of the body in gross configuration or minute structures; second, rebreathing of expired air, from lack of ventilation; third, defective and innutritious diet. Imperfectly developed chest and lungs are commonly noticed in civilized countries, but too little attention is paid to correction of these defects. In two hundred and fifty phthisical subjects, averaging 5 feet 5½ inches in height, the chest-measurement was only 31½ inches, instead of 37 inches, the proper circumference for that height. Suggestions were offered for exercising the lungs and chest-muscles as a prophylactic measure.

DR. P. H. KRETZSCHMAR, of Brooklyn, read a paper entitled

NOTES ON THE PREVENTION OF PULMONARY CONSUMPTION.

Efforts to prevent the development of this disease should be concentrated in two directions: First, to destroy, or lessen the number of tubercular bacilli floating in the air; and, second, to prevent the human organism from developing a disposition to acquire consumption.

I. Since total destruction of the deadly bacilli is hopeless, we must diminish their number. Isolation of patients has been tried a hundred years in Naples and Portugal without any marked diminution in the prevalence of the disease. Isolation of all consumptives, unless by international law, is infeasible as well as cruel. The teachings of Dr. Cornet, of Berlin, should be our guide. His experiments demonstrate that (1) the consumptive *per se* is not, but (2) the sputa are, the source of danger. It is of vital importance to destroy the bacilli in the expectorations as soon as possible. The spittoon should find more universal use. Carpets should be banished from homes of consumptives. A pocket-flask should be carried for use in place of the handkerchief, when spittoons cannot be found. Expectorations should never be swallowed, not only to avoid self-infection, but contamination of the fæces.

II. Rokitansky gives the characteristics of the "phthisical habitus" as a small heart in a chest of small antero-posterior diameter and long perpendicular dimensions, large lungs, and proportionately small abdominal cavity. The disposition to acquire the disease is oftenest found in the offspring of consumptive parents. The views of Dr. Brehmer, of Gœrbersdorf, are indorsed; viz., 1. If there are many children in a family, those born after the sixth are apt to develop consumption. 2. If several children in a family are born at short intervals, the younger are liable to develop the disease. 3. If the offspring of healthy parents, born under the above conditions, escape the disease, their children are apt to develop it. Patient and prolonged investigation leads to the belief that "only a small proportion of phthisical patients can be found who do not possess a family history which either demonstrates a directly inherited tendency, or a directly or indirectly acquired disposition toward the development of the disease." Of 506 cases at Dr. Brehmer's sanitarium, 184 (36 per cent.) were offspring of consumptive parents or grandparents; 147 (29 per cent.) had an acquired disposition, being from families where there were many children, or where the mother had children rapidly; 153 were children of parents who were born under the above conditions but had themselves escaped the disease. Dr. Brehmer's statistics have been verified in the experience of the writer. Certain functional or structural changes in young subjects indicate danger of future tubercular infection. They are: 1. Anatomical defects in the chest, which are a part of the "phthisical habitus." 2. The fact that the subject is a small feeder. 3. The fact that during the age of puberty the subject has suffered from palpitation of the heart. 4. The fact that at the same time, and frequently for years afterward, there has been epistaxis. Transfer of threatened subjects to a proper climate in a high altitude will save many lives. Out-of-door life is also advisable.

In the discussion which followed DR. HIBBERD, of Indiana, advocated the importance of proper clothing and the cultivation of a vigorous condition of general health to enable the system to withstand disease.

DR. PLAYTER opposed the theory of heredity of tubercular disease, and defended his belief in small lungs as predisposing to consumption.

DR. CYRUS EDSON, Chief Inspector of the New York City Health Department, read a paper on

DISINFECTION OF DWELLINGS BY SULPHUR DIOXIDE.

An extended experience in the use of this fumigant has led to the belief that it is a thorough and almost perfect destroyer of the infection of the acute exanthemata and diphtheria. The evidence, however, is mainly circumstantial. Statistics were quoted from the records of the department to show the non-recurrence of disease where premises had been fumigated by this agent.

DR. G. M. STERNBERG, of U. S. Army, sustained the position of the paper, and said that points of vaccine virus exposed to the fumes of sulphur dioxide had proved incapable of producing vaccinia, while some of the same virus not thus exposed had been efficient in the opposite arms of the same patients.

DR. RAYMOND, of Brooklyn, spoke of the importance of having the sulphur burned "in the presence of moisture," as recommended by the Committee of the Association on Disinfectants. Health-boards are not explicit in directing this. The purpose is not to prevent fire, and should not be used to wet walls or articles in the room, as that causes bleaching and corrosion by the acid formed. There are some reasons to doubt that all immunity from recurrence of the diseases is due to the fumigation; vaccination and other measures usually accompany the disinfection, and the same families are not so susceptible to a second infection, if they escape the first, as fresh subjects would be.

The subject was further discussed at some length by Drs. Bryce, Maxwell, Chapin, Van Derbergh, and Durgin.

A paper by DR. JOHN H. RAUCH, Secretary of the State Board of Health, Chicago, Ill., entitled "The Utilization and Purification of Sewage," was read by title only, as the author was absent, and the meeting adjourned.

EVENING SESSION.

REV. CHARLES R. TREAT, of New York, made an address (illustrated by numerous stereopticon views) on the subject of

SANITARY ENTOMBMENT.

After reviewing the practice of earth-burial in churchyards and cemeteries, and showing the injury to the health of residents adjoining such places, he spoke of the effect of the atmosphere upon corpses exposed in cold or dry climates, and compared the result obtained by embalming. A method of entombment on a large scale within a small area, by a sort of co-operative building plan, was then suggested. The bodies, enclosed in the apartments thus provided, would be subject to a constant current of desiccated air, to secure the same effect as that of the atmosphere in Arizona, Palermo, or Western Peru.

DR. BENJAMIN LEE, Secretary of the Pennsylvania State Board of Health, Philadelphia, read a paper on the question,

DO THE SANITARY INTERESTS OF THE UNITED STATES DEMAND THE ANNEXATION OF CUBA?

Among the reasons for an affirmative answer were the following: The constant communication between this country and Havana, which is a notorious breeding-place of yellow fever; the only means of eradicating the disease is a proper system of sewerage and drainage, which the Spanish Government is not likely ever to undertake; a single wide-spread epidemic of this disease in the United States would cost more than the purchase-money of Cuba; leprosy prevails to a serious and constantly increasing extent in Cuba, is absolutely unrestricted, and already has obtained a foothold in the ports of this country in closest communication with Cuba.

Following this paper, DR. PRINCE A. MORROW, of New York, gave a series of stereopticon views showing the different stages and varieties of leprosy.

DR. MAXWELL, of Florida, differed with the paper read on the expediency of annexing Cuba, on the ground that it is useless to attempt to prevent the entrance of a disease—yellow fever—which already exists in this country.

A paper on "Railway Sanitation," by DR. S. W. LATTA, of Trenton, N. J., was read by title, and will appear in the "Transactions" of the Association.

FOURTH DAY, FRIDAY, OCTOBER 25TH—MORNING SESSION.

The closing session of the Association began at 9 A.M., with announcements by the Executive Committee, through the Secretary, DR. I. A. WATSON. The resolutions already recorded were favorably reported and adopted.

A report from the Advisory Council was then received, and by its adoption the Association decided to hold the next meeting at Charleston, S. C., not earlier than November 1, 1890.

The following officers were elected, on one ballot, for the ensuing year: *President*—Dr. H. B. Baker, of Lansing, Mich. *First Vice-President*—Dr. Frederic Montizambert, of Quebec. *Second Vice-President*—Dr. Joseph H. Raymond, of Brooklyn. *Secretary*—Dr. Irving A. Watson, of Concord, N. H. *Treasurer*—Dr. J. B. Lindsley, of Nashville, Tenn. *Executive Committee*—Drs. L. F. Salomon, of New Orleans, La.; William Bailey, of Louisville, Ky.; H. B. Horlbeck, of Charleston, S. C.; Walter Wyman, of Washington, D. C.; J. F. Kennedy, of Des Moines, Ia.; P. H. Bryce, of Toronto, and the twelve ex-Presidents of the Association.

A new Advisory Council, composed of a member from each State and Province, was announced, and a resolution of thanks to the city officials, the New York Quarantine officer, the Local Committee, and others, was adopted.

D. E. SALMON, D.V.M., Chief of the Bureau of Animal Industry, Washington, read a paper on "The Necessity for a More Rigorous Inspection of Meat-producing Animals at the Time of Slaughter."

DR. A. M. GIHON, U. S. Navy, read a paper prepared by DR. R. O. BEARD, of Minneapolis, Minn., entitled

THE CAUSES OF INFANT MORTALITY.

They were classified as arising from the bacillus tuberculosis and from nutritional and nervous disorders. The prevention of infantile disorders would be greatly promoted by the education of the people in sanitary matters. One of the great mistakes of the present day was to regard infants' stomachs as of a different character from those of adults. The too frequent feeding of infants is a vice almost universally prevalent and quite generally countenanced, or actually encouraged by the profession. It is grounded in custom, as absurd as the incasement of Chinese infants' feet in permanent baby-shoes. It is intrenched behind that most dangerous of all arguments, among the ignorant, the argument from experience; while it is condemned by every careful observation of the lower orders of animal life, and by every physiological principle bearing upon infancy.

DR. JEROME WALKER, of Brooklyn, in discussing this paper, called attention to the agreement in the recommendations of the three papers on this subject read before the meeting, and thought the subject of infant-mortality might well be referred to a committee to collate statistics and report to the Association.

DR. J. H. RAYMOND concurred, and moved the appointment of such a committee with Dr. Walker as chairman. The matter was referred to the Executive Committee with power.

DR. G. C. ASHMUN, of Cleveland, O., said that no class of the community needed instruction more in regard to this matter than the medical profession.

DR. W. M. SMITH, of New York, said a more intelligent observation of death certificates by Boards of Health is needed. When practitioners attribute mortality to "debility," "marasmus," or "heart-failure" the certificates should be returned for correction.

Drs. Rohe, McDonald, Hibberd, and Jaynes also spoke on this subject.

Two papers by Edgar Richards, microscopist of the United States Treasury Department, upon "American Methods of Manufacturing Oleomargarine," and "The Oleomargarine Law of the United States," were read by title and ordered included in the proceedings of the Association.

## AMERICAN DERMATOLOGICAL ASSOCIATION.

*Thirteenth Annual Meeting, held at Boston, Mass., September 17, 18, and 19, 1889.*

(Continued from p. 471.)

SECOND DAY, WEDNESDAY, SEPTEMBER 18TH—MORNING SESSION.

DR. HARDAWAY, of St. Louis, read the first paper, entitled

LUPUS ERYTHEMATOSUS, ENDING IN DEATH.

The patient was a man, twenty-three years of age, whose lupus erythematosus of the face followed an eczema which had itself appeared subsequent to rhus-poisoning.

Improvement took place for a time under Klotz's plaster and a salicylic and sulphur ointment, but the lymphatic glands became implicated; the neck aumessd a board like hardness. The temperature reached 104.5 F., due, the reader thinks, to the adenitis. Suppuration took place in some of the glands, while gland after gland became involved in a tuberculous process. The patient died suddenly of pneumonia.

DR. TAYLOR was inclined to regard such a case as one of a subacute infective process.

DR. GREENOUGH said lupus erythematosus was undoubtedly present, but part of the dermatitis might be due to local irritants.

Dr. Taylor, of New York, read a paper entitled

A HITHERTO UNDESCRIBED FORM OF NEW-GROWTH OF THE VULVA.

The paper was based upon a long and careful observation of two cases in Charity Hospital. In one case the growth was subsequent to chancroids, and its nature was benign and purely inflammatory, as shown by microscopical examination made by several careful pathologists. The author does not accept at all the views of those observers who regard these hypertrophic and ulcerative vulvar lesions as identical with lupus or the result of syphilis, or due to tuberculous infection, and thinks the term "esthiomene" should be discarded. He considers most of these non-malignant growths as simple hyperplasias of the tissues induced by irritations, inflammations, and traumatisms. Many cases are due to essential and specific syphilitic infiltrations. Others are caused by hard œdema, and still others by simple hyperplasia in old syphilitic subjects who suffer from chronic ulcerations of the vulva long after all specific lesions have departed. In healthy persons the same irritating causes might only result in vulvitis. Some rare cases are those of simple inflammation resulting from antecedent ulcerative and inflammatory conditions.

The surface of the new-growth which involved the perineum in these cases was of a maroon or chocolate color, and was either dry or gave rise to a scanty reddish serum. Both patients had died.

Dr. Bronson had seen one of the cases, which to him resembled an epithelioma. He could not regard it as simply inflammatory.

Dr. Heitzmann said the process was surely a malignant neoplasm, and he had decided after examination of the specimen that it was sarcomatous. Lack of ulceration, temporary cicatrization, flatness of tumor, and death, all pointed to sarcoma.

Dr. Robinson agreed with the last speaker.

Dr. Taylor in closing said he could vouch for the clinical features. The histological part of the examination had been conducted by men whose opinions he respected, still he should be glad to have anyone present examine all of his specimens, and to consider the diagnosis still *sub judice*. No evidences of metastatic growth had been observed.

SOME SUGGESTIONS IN DERMATOLOGICAL THERAPY

was the title of a paper by Dr. Sherwell, of Brooklyn, in which he first considered

A SIMPLE METHOD OF TREATING SCABIES,

which consisted in the application of dry powdered sulphur to the body as well as to the bedclothes. A mild oil may be rubbed over the skin beforehand. Eight cases were thus treated with good success.

ECZEMA ANI

was often found due not only to a slight fissure at the margin of the anus, but to one just within the sphincter. Hard-rubber bougies should be introduced each night and left for ten minutes.

ECZEMA AND SYCOSIS OF THE UPPER LIP

are very rebellious, and because of their great annoyance require careful treatment of the nose, upon the acrid secretions of which they usually depend.

It is probable, too, that the gases from an ozæna may also prove irritant.

Dr. Bulkley said these cases were very rebellious. He had not thought of the gases being sources of irritation, still they might be. In some cases we must go back of the local nasal affection to the systemic trouble on which that depends.

Dr. Zeisler said these cases were so chronic because complicated by a distinct disease of the roots of the hair. He looked upon the nasal catarrh as of myotic origin, and upon the affection of the lip and hairs as of direct infection.

Dr. Bulkley, of New York, read a paper entitled

WHAT REAL VALUE HAVE MINERAL WATERS IN THE TREATMENT OF THE SKIN?

which will appear in a future issue of The Record.

Dr. Hardaway had always been able to explain the benefit obtained at springs by other facts than the mineral ingredients.

Dr. Sherwell was glad to hear a voice raised against the harm done by springs in general, as now carried on. He had often seen their ill effects.

Dr. Graham spoke of the Preston Springs, in Canada, at which resort some of his patients with eczema had received marked benefit.

Dr. Bulkley said he had thought the Missisquoi Spring of Vermont of some benefit in cancer cases. The water contains a small amount of silica.

Dr. Heitzmann read a paper entitled

DERMATITIS PAPILLARIS.

As is well known, a slight irritation may cause a pseudo-keloid. After trauma exuberant outgrowths at times take place, and Kaposi has named such a condition of the scalp *dermatitis papillaris*. It is similar to myxo-fibroma. The Hebrew race appears to show a predisposition to this affection. The reader has recently had two cases under observation, both of this race. In one the lesions were the size of a pea and situated upon the chin, and in the second case the occiput and neck were affected. They are hard to the touch, raspberry-like, cicatricial tissue is present, and here and there bunches or tufts of hair difficult to extract. Hebra warned against operation. Kaposi advises the use of scissors or knife if the tumors grow up. Heroic treatment, the reader thought, should be avoided, and caustics only be applied in a gentle way, such as the solid stick of silver nitrate every two weeks. He had found a three per cent. alcoholic solution of salicylic acid most efficacious. Such cases are rare.

Dr. Fox said he had seen one of the cases reported. The size of the growths was decreased by electrolysis. They were subsequently removed by operation in Vienna, but returned with increased vigor. He had also treated a case on the occiput of a negro. He regarded it as the same affection as keloid, modified by location. All who spoke had observed cases of the affection, some preceded by sycosis, and some resembling keloidal growths.

Dr. Zeisler read some

CLINICAL NOTES ON SYCOSIS.

He had found little in literature regarding sycosis capillitii, in which here and there were little tufts of hair attended with itching, burning, and pain in the scalp. Two personal cases were reported in which epilation, sublimate lotion, and ammoniated mercury ointment at night had given good results. He had seen keloid in sycosis.

Dr. Robinson believed in a sycosis of the scalp, the lesions of which are isolated and the secretion serous. He thought the ground should be made unfavorable for the development of cocci by internal treatment.

Dr. Bulkley spoke of a follicular inflammation of the scalp in which a small scar resulted and caused a localized baldness. He regarded it as constitutional.

Dr. Denslow reported a case, seen during the year, in which deep-seated abscesses had existed for several years upon the scalp, and had regarded it as an acne. Large doses of ergot had good effect.

Dr. Klotz agreed with Dr. Robinson that pustules were secondary and not essential features.

Dr. Graham had seen the lesions of a sycosis disappear during a typhoid, and recur as soon as the patient was well, so he did not regard it wholly as a local disease.

Dr. Zeisler answered that we know in febrile disturbances scabies, eczema, and other skin eruptions disappear. We know that acne, eczema, and sycosis are distinct affections, but his two cases were so similiar to sycosis of the beard that he had named them as he did.

Dr. Sherwell read a paper entitled

RELAPSE OF PEMPHIGUS FOLIACEUS AFTER ELEVEN YEARS' QUIESCENCE.

The first attack was in 1877, the second in 1878, and the third during the present year. Bullæ gradually appeared, until nearly the whole body was covered. Subsequent dry scales formed, and made the case resemble a pityriasis rubra. The same author read a second paper on

IMPETIGO HERPETIFORMIS.

The patient had borne several children, and never had an eruption until three years ago, when vesicles formed upon the arms and legs, and soon became pustular. In the present attack nearly the whole body was implicated, and several relapses took place. When seen by the reader the lesions were impetiginous, and a grave prognosis was made. Improvement, however, took place, and furfuraceous desquamation followed. He believed it a similar process to Duhring's dermatitis herpetiformis. Hospitalism may have had something to do with the fatal result in the Vienna cases.

Dr. Heitzmann asked how this could be the same affection as Kaposi's impetigo herpetiformis, in which pustules from the first were necessary for a diagnosis if vesicles were observed early.

Dr. Zeisler referred to his published case, which was typical, and proved that the disease could occur here. He believed impetigo herpetiformis a disease *sui generis*.

Dr. Bulkley thought herpes gestationis distinct from this affection.

Dr. Robinson had seen the subject of the first paper, and it was surely pemphigus foliaceus.

Dr. Sherwell said that while all the lesions in his case of impetigo were not pustular from the first, some were.

ACNE CACHECTICORUM.

Dr. Bronson read a description of a case of rare eruption in a young boy. The lesions were papular, tubercular, and pustular, and occurred as grouped lesions, coming in successive crops on various parts of the body, the face, back, and nates being the regions most affected. The face about the eyes was very œdematous, and the patient's general condition was anæmic and below par. There were many deep-seated dermic abscesses, and pits like those of small-pox. Arsenical poisoning had been thought of, but excluded.

Dr. Morrow thought the case which he had seen recalled the features of arsenical poisoning.

Dr. Allen had also examined the patient, and, while agreeing in the diagnosis, had thought there might still be poisoning by arsenic as a basis.

The Secretary read a paper by Dr. Stelwagon on

THE ALLEGED TOLERANCE OF THE IODIDES IN LATE SYPHILIS.

The author is of the opinion that the tolerance is not more marked in syphilitic than in non-syphilitic patients. A number of cases were reported to illustrate how frequently the iodide is not well borne. His own experience corresponds to that of Haslund, that large doses could be given in psoriasis with an equal freedom from iodism to that seen in syphilis.

Dr. Taylor said that Wood's conclusions drawn from nervous cases were faulty. We are apt to give up the use of iodide too early because of a beginning coryza, while, if pushed, it would often be found well supported.

Dr. Greenough said that some patients will bear large doses when small ones will cause bad symptoms.

Dr. Denslow added his experience in one case of undoubted syphilis. The patient could not stand even the smallest dose.

Dr. Shepherd had found the iodide of ammonium better tolerated than the potassium salt.

Dr. Bulkley had found the conjoint administration of arsenic to increase the tolerance.

The next meeting will be held at Richfield Springs, September 2, 1890.

The officers elected for the ensuing year are: *President*—Dr. P. A. Morrow, of New York; *Vice President*—Dr. G. H. Tilden, of Boston; *Secretary*—Dr. G. T. Jackson, of New York. Two new members were elected: Dr. J. T. Bowen, of Boston, and Dr. C. W. Allen, of New York.

# Correspondence.

## OUR LONDON LETTER.

(From our Special Correspondent.)

THE FIRST OF OCTOBER—OPENING OF THE MEDICAL SCHOOLS—THE INTRODUCTORY LECTURES—THE SANITARY CONGRESS AT WORCESTER—ADDRESSES BY THE PRESIDENT AND DR. G. WILSON—PAPERS BY DR. TRIPE, MR. CASSAL, AND MR. WILLIS BUND.

London, October 2, 1889.

The first of October is a date noteworthy alike to the profession and the public. To the latter it marks the commencement of pheasant-shooting, while to members of our profession it signalizes the opening of the medical schools in London and the provinces (not in Scotland, where the winter session commences later). Few there are to whom the first of October is not a specially significant date. Even among those quite unconnected with any of the medical schools, it recalls the memory of early studies and struggles. Although much abused, the "introductory lecture" still survives at many schools, though what useful purpose it serves, or can serve, it would be difficult to say. At University College the introductory lecturer for the present year (Mr. Rickman J. Godlee) went so far as to say in his lecture that the custom of giving introductory addresses was laborious to the giver and useless to the student. At King's College the lecturer was Sir Albert Rollit, M.P. He referred to the progress made by the medical profession in recent years as regards their relationship to the State, but considered there was room for further improvement as to this. He thought the establishment of a local university for London, in addition to the existing university, would be of benefit. He also urged the importance of keeping logic in the foreground of their studies unless they went in for theology, when, happily, faith naturally supplanted logic. At St. Thomas's Hospital the address was given by Mr. William Anderson, Assistant-Surgeon to the hospital. It was chiefly devoted to an historical review of the progress of medicine and surgery in Europe, from the beginning of the sixteenth century to the present time. At St. Mary's Hospital Dr. Robert Maguire was the lecturer, and his lecture was devoted mainly to an account of the history of preventive inoculation. When once germs had been introduced into the body we could, he said, rarely control their action. To obtain full protection from their action the body must be rendered incapable of being attacked by the germs. In many cases protection was given by a former attack of the disease from which the animal had recovered, and the object of protective inoculations was to produce a similar result. M. Pasteur's work was discussed and criticised at some length. At the Middlesex Hospital Mr. Bland Sutton discoursed on "intellectual blindness." To illustrate blindness in observation, he mentioned a number of simple defects commonly overlooked by students. He also gave a brief account of cretinism and pointed out that, though occurring mainly in Alpine districts, it was now clear that cretins were born in this country, and that the disease was not confined to human beings but occurred also in calves and dogs. Dr. P. S. Abraham gave the lecture at the Westminster Hospital and dwelt upon the advantages of a careful training. He was of opinion that the medical curriculum should be extended to not less than five years

to give a man a chance of applying himself. At St. George's Hospital the address was given by Dr. Clifford Allbutt. At the remaining hospitals—Guy's, St. Bartholomew's, Charing Cross, and the London—there was no lecture.

The Sanitary Congress took place last week at Worcester, under the presidency of Mr. G. W. Hastings, M.P. In the presidential address various influences bearing upon public health were referred to. In speaking of the sanitary condition of houses and habitations, the necessity of proper appliances for the disposal of sewage was especially pointed out. Mr. Hastings said he was himself strongly in favor of placing the liquid sewage on the land directly. Associated with this subject was the necessity of looking after the construction of drains and sewers, and all the requisite appliances. Excellent work was being done by the Plumbers' Company, in London, by training and registering skilled workmen for the purpose. Another leading influence on health was that of occupation. Too many trades in this country tended to produce disease. The beautiful porcelain manufacture in Worcester still occasioned, in some instances, danger to the health of those engaged in it; but he was glad to say that a great deal had been done to lessen the danger. Inventors were continually at work in various occupations, not only to improve productions, but to improve health. One of the most remarkable of these was the new machine for bottle-making. Under the old plan of making bottles by blowing, the lungs of the workmen had been so much affected that their lives extended to not much more than thirty years in duration. With the new machine all blowing was done away with, and, as he had pointed out at Newcastle (in a discussion in the Mechanical Section of the British Association), there was no reason why the longevity of bottle-workers should not equal that of other artisans. The importance of preventing river pollution and of exercising sufficient control over dairies was dwelt on, and recent sanitary enactments referred to, among them being the bill rendering compulsory the notification of infectious diseases, which Mr. Hastings spoke of with approval.

An interesting address was given by Dr. G. Wilson on "The Policy of Prevention in Some of its Social Aspects," in which it was pointed out that an immense amount of disease was due to heredity, errors in diet, abuse of luxuries, overwork and worry, and other preventable causes. Dr. Wilson pointed out that, as to the first of these causes —heredity—in addition to the diseased offspring resulting from unhealthy parentage, multitudes of maimed and doomed children resulted from unsuitable or imprudent marriages, apart from diseased parentage. Unthriftiness in marriage too often led to intentional neglect of the children amounting to culpable homicide. It largely accounted for false thrift, under the name of infant life assurance, spreading its baneful influence even into innocent village communities. He doubted whether public opinion was advanced enough to enforce a certificate of health on the part of persons about to marry, but he thought some check should be put upon the appalling waste of infant life by prohibiting marriages unless the man could produce reasonable proof that he was in a position to maintain a wife.

Among the papers read at the Congress was one by Dr. Tripe, Medical Officer of Health for Hackney, on "Winds and their Sanitary Effect." A northeasterly wind, so much dreaded in this country in winter, passed over the northern portion of Russia, including Siberia, before reaching us, and was consequently cold and dry. It was frequently treacherous in summer, and caused colds. Easterly winds, which passed over part of Russia and Germany, were dry and biting, having the character of a land wind a little tempered by the German Ocean.

Mr. C. E. Cassal read a paper on "The Extension of Public Analysis," which led to some discussion. The view was expressed that the original adulterators of foods, being the great offenders, should be proceeded against, and not the humble shopkeepers, who were, in most cases, ignorant of the adulterated character of the goods which they sold. Mr. J. W. Willis Bund read a paper suggesting the establishment of a standard for effluents from sewage works. It was followed by a discussion in which attention was directed to the great extent to which fish are poisoned in our streams by sewage.

## OUR PARIS LETTER.

(From our Own Correspondent.)

CHLORALAMIDE—OBTAINING ATROPHY OF THE EYE BY OPERATION—THE RELATIVE ACTION OF THE IODIDES OF POTASH AND SODA—SACCHARIN A DISTURBER OF DIGESTION.

PARIS, October 11, 1889.

CHLORALAMIDE is the name of a substance recently introduced into therapeutics as a useful hypnotic. It consists of a combination of chloral and of formanide. It is obtained under the form of colorless crystals, soluble in about nine parts of water, or in one and a half of spirit. Numerous researches on animals and on man have been made, and it has been found that this new product produces sleep at a dose of from one to four grammes. The sleep is produced less rapidly than with chloral, but more quickly than with sulphonal, generally in half an hour, whereas it is induced in a quarter of an hour with chloral. No injurious action has been observed on the digestive tube, nor any consecutive and persistent troubles which are manifested after the employment of sulphonal. It is easily administered in powder, either in wafers or in wine or tea, three grammes of chloralamide corresponding with two grammes of the hydrate of chloral. When once sleep is induced, the effects last from six to eight hours. But no effect can be obtained in delirious patients or those which are very much excited. It succeeds, on the contrary, in subjects affected with insomnia after alcoholic excesses, and in neuropathic and hysterical subjects. Chloralamide presents, besides its little influence on the sanguineous pressure, that which permits it to be prescribed without danger to patients who are the subjects of organic affections of the heart, the advantage of not being disagreeable to take, nor does it give rise to any disagreeable sensation after waking from the sleep induced by it.

In the *Journal d'Oculistique* Dr. Fano proposes an operative expedient with the view of obtaining the atrophy of the eye, and substituting it for the extirpation of that organ. The operation consists in puncturing the vitreous body, which is followed by an abundant escape of the vitreous humor. This idea was suggested to him by the observation of what takes place after certain operations for cataract by extraction, in the course of which the hyaloid membrane is accidentally wounded. The rule, in the cases of this kind, even when the extraction ends favorably, is consecutive atrophy of the eye. The author submits the following case as an illustration: A young girl of seventeen, affected with a congenital buphthalmos of both eyes; one of these, the right, was injured by an instrument which pushed it outside the orbit, and produced at the same time a rupture of the blood-vessels of the superior eyelid and of the sub-conjunctival cellular tissue. Instead of proceeding immediately to the extirpation of the globe, he practised a large puncture of the cornea and of the part attached to the sclerotic. A certain quantity of the aqueous humor, followed by vitreous humor mixed with blood, escaped. At the end of three weeks the eye was atrophied, without the development of any inflammatory accidents. He subsequently had two occasions to put this mode of treatment into execution, and with equal success.

Professor Germain Sée has made a very important communication at the Academy of Medicine this week, on the relative action of the iodide of potassium and the iodide of sodium. The learned professor asserts that the action of these two salts is very different, the one from the other; the sodium acts neither on the heart nor on the blood-

vessels, whereas the potassium has a well-marked action on these organs. If one injects into the veins of a dog one gramme of the iodide of potassium, it is seen that this animal well supports this dose, and even three grammes may be injected without any bad effects. Far from being a poison, the iodide of potassium has a tonic action on the heart, which places it second only to digitalis and renders it useful in the treatment of the greater number of the affections of the heart; but in the nervous affections of that organ it is more injurious than useful. As regards the iodide of sodium, it has no action whatever on the heart, and cannot in consequence replace the iodide of potassium.

Dr. Fourrier, of Compiègne, writes that since it has been known that saccharin impedes the action of the digestive fermentations, and that clinical observation has shown that its ingestion was susceptible of troubling more or less profoundly the acts of digestion, it has been prohibited as a substance which may be employed for alimentary purposes. It has, however, remained a medicament, and according to the researches of Dr. Constantin Paul, it may be placed in the class of antiseptics. As such, Dr. Fourrier remarks that it was rational to try it in the treatment of aphthæ, and this has been fully confirmed by clinical experience. Dr. Fourrier treated ten cases of aphthæ consecutive to measles by painting the inside of the mouth with a solution of saccharin. Eight times the milky patches had disappeared in from twenty-four to thirty-six hours; twice only they resisted the treatment for three days, but this was attributed to the paintings not having been properly practised. The following is the solution employed by Dr. Fourrier: Saccharin, one gramme; alcohol, fifty grammes. A teaspoonful to be put into half a tumbler of water, with which the mouth should be painted five times a day. A more concentrated solution would be dangerous, as it would irritate the mouth, as shown by several cases which came under Dr. Fourrier's observation.

## Army News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 20 to October 26, 1889.*

WAKEMAN, WILLIAM J., Captain and Assistant Surgeon. Relieved from duty at Fort Walla Walla, Wash. Terr., and will report in person to the commanding officer, Fort Bidwell, Cal., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

DAVIS, WILLIAM B., Captain and Assistant Surgeon. Relieved from further duty at Fort Porter, N. Y., and will report in person, upon expiration of his present sick leave of absence, to the commanding officer, Fort Preble, Me., for duty. Par. 6, S. O. 248, A. G. O., October 24, 1889.

RAYMOND, HENRY I., First Lieutenant and Assistant Surgeon. Upon being relieved from duty at Fort Bidwell, Cal., will report in person to the commanding officer, Newport Barracks, Ky., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

SHANNON, WILLIAM C., Captain and Assistant Surgeon. Relieved from duty at Fort Yates, Dak., and will report in person to the commanding officer, Fort Apache, Ariz. Terr., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

CHAPIN, ALONZO R., Captain and Assistant Surgeon. Relieved from duty at Newport Barracks, Ky., and will report in person to the commanding officer, Fort Yates, Dak., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

MEARNS, EDGAR A., Captain and Assistant Surgeon. Granted leave of absence for two months. Par. 5, S. O. 244, A. G. O., October 19, 1889.

KENDALL, WILLIAM P., First Lieutenant and Assistant Surgeon. Leave of absence extended one month. Par. 6, S. O. 244, A. G. O., October 19, 1889.

CLENDENIN, PAUL, First Lieutenant and Assistant Surgeon. Relieved from duty at Fort McIntosh, Tex., and will report in person to the commanding officer, Camp Eagle Pass, Tex., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

EGAN, PETER R., Captain and Assistant Surgeon. On being relieved from duty at Camp Eagle Pass, Tex., will report in person to the commanding officer, Fort McIntosh, Tex., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

BRECHEMIN, LOUIS, Captain and Assistant Surgeon. So much of paragraph 2, S. O. 241, October 16, 1889, as directs him to report for duty at Fort Apache, Ariz. Terr., is revoked. He will report in person to the commanding officer, Presidio of San Francisco, Cal., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 26, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 50 | 14 |
| Scarlet fever | 40 | 5 |
| Cerebro-spinal meningitis | 0 | 1 |
| Measles | 41 | 2 |
| Diphtheria | 78 | 16 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

ABSURDITIES AND CRUELTIES OF WOMAN'S DRESS.—At the recent meeting of the British Association for the Advancement of Science Mrs. C. Stopes read an interesting paper on "Psychological, Physiological, and Physical Aspects of Dress." Mrs. Stopes confined herself to considering the attire of her own sex, many of the absurdities of which she denounced. The aim of dressmakers, she said, seemed to be to make women incapable of free motion or prompt action. Prompt physical action, in case of an emergency, was almost impossible to a woman, and by disuse her powers became injured. Long dresses gave rise to uncleanliness and the risk of receiving infection of various kinds from street dust swept up. The inequalities and disproportions of clothing were then dwelt upon, after which Mrs. Stopes pointed out the injury to health caused by using high heels. High heels were valuable only when walking up hill; a patent might be taken out for movable heels to be screwed on when ascending mountains. But the woman who wore high heels was perpetually walking down hill. The habit of wearing tight stays was an evil of national importance. If we heard of a government punishing malefactors by tight lacing we should cry shame on it for cruelty and demand the cessation of so horrible a punishment. Nature revenged herself, for none of the compressed organs could act healthily and freely.

COMPARATIVE OBSTETRICS.—A giraffe has been born in the Cincinnati Zoo, it being the first delivery of this kind that ever took place in this country. It is said to have been a head presentation and to have been a long labor, the baby being nearly six feet from tip to toe when dropped.

### THE TREATMENT OF HERNIA.[1]

BY JOSEPH D. BRYANT, M.D

NEW YORK.

CUSTOM, in this Association, declares in favor of a formal discussion of some special subject of general interest. Fate decreed that it fall to the lot of the reader to outline and open the discussion, also to indicate those who have so kindly consented to honor and to enlighten the occasion with their presence, and with the results of their labors. The treatment of hernia is the special subject that was submitted by "the powers that be," for our consideration, and now we—the writers—will submit the conclusions to your consideration, hoping that these conclusions will justify the previous action of the "powers," at least in some degree.

The subject, hernia, is an ancient one, and has associated with it the dust and traditions of the earliest times of medical and surgical matters. It can be safely assumed, I think, that the consideration of means of relief from this affliction was but a step behind the first occurrence of the affliction itself; and the age of the affliction is best measured by the length of the time of the establishment of the present relations of the abdominal contents and their walls with each other.

The first person who had the first hernia was the first one to contemplate means of relief from it, and no doubt soon learned to seek the same relief in the recumbent posture, and from manual pressure, that these measures afford to-day. The mechanical treatment of this affliction had its inception, no doubt, at about the time that the first unfortunate sufferer had succeeded, after much labor and pain, in reducing a strangulated viscus. He appreciated at once that the abdominal contents must be kept in their proper places; and he had, without doubt, noticed the fact that the recumbent posture met this requirement; but to remain lying was then, as now, neither wise, pleasant, nor remunerative. To retain the viscus in the proper place by manual pressure while in the erect posture, was recognized to lead to improvidence, to encourage impertinence, and to end in despair. It contemplated a too practical application of that good biblical maxim that teaches "Let not thy left hand know what thy right hand doeth." The use of bandages and soft compresses for the retention of hernial protrusions was recommended by Celsus, near the first century, and, too, cures were claimed by him to follow their use, especially in young children. Galen confirmed the treatment of Celsus, and, about five centuries later, Theodorus Ætius emphasized the method and the results. Pads of wood and of iron, held in position by a non-elastic soft girdle, were employed in Italy in the thirteenth century. In the fourteenth and fifteenth centuries, Bernard de Gordon and Gatanaria advised the use of an iron girdle, which, however, was soon exchanged for the hard-pad and soft-girdle appliance previously in use. In the sixteenth century, Fabricius Hildanus devised a truss of flexible soft iron, which could be moulded to fit the form of the patient. It is said that to Matthias Major belongs the credit of having first employed, in 1665, a truss with an elastic steel spring. The time at my disposal will not permit me to dwell at length on the further development made in hernial appliances. In fact, it is hardly necessary, since it is now only requisite to attach the hard pad of the thirteenth century to the elastic steel spring of the seventeenth, to form the substantial construction of the majority of the serviceable trusses of the nineteenth century. The greater number of medical men of the present day are blissfully ignorant of the truss armamentarium now in the market, also of the measurements, means, and method of fitting them properly to patients. The patients thus afflicted are relegated to the "instrument makers," or to other mechanical agents, for the proper truss and appliance, and the application of it. In a large number of cases, no doubt, this course on the part of the medical man is actuated by the sense of his own inability to meet the demands of the case; when this is the true cause, while we may commend him for his sincerity, still we must respectfully submit that he is a much too willing exponent of the sentiment that teaches "Where ignorance is bliss, 'tis folly to be wise." I will not say more on this point, but will avail myself of the privilege extended by law to those who are not required to testify as to matters that may criminate themselves. The consideration of the worth of trusses should contemplate the elements of the instrument that contribute to cure, to comfort, to convenience, to cheapness, and to durability.

That ruptures are cured by the proper use of trusses, there can be no doubt; but the number of substantial cures resulting is, unfortunately, small. It is impossible to estimate, with any degree of practical precision, the percentage of cures resulting from hernial appliances, since these appliances are commonly worn for the comfort and convenience they afford, rather than for the purpose of a cure. Although it is proper to say that there are many trusses extolled for the certainty of cure, these, however, soon become associated with other things of a worldly character, that contribute to heart-sickness by reason of "hope deferred." I have at this time under observation several patients who have worn trusses for two to five years by my direction, and they still continue to wear them by the same advice, although anxious in a few instances to lay them aside, because, as they express it, "It has not been down in months." It is, in my judgment, unwise to dispense entirely with the use of the truss, no matter how sure the patient, or even the doctor, may be of cure. In fact, the greater security lies in the judicious continuance of the use for patients who are certain of having recovered. Persons under twenty years, especially children, who wear the appliance faithfully, may expect to be markedly benefited, if not cured, when suffering from either form of inguinal or femoral hernia of a reducible nature. The cure contemplated, however, is one that does not provide for all physical contingencies of human life. It is a cure in the sense that the structures may be then as able to withstand the effects of force as before the primary appearance of the hernia. It is a cure in the sense that the ordinary vocations of life may be safely met; while all others should be feared to the extent of seeking a safe retreat behind the friendly support of the ubiquitous truss again.

It is my practice, when the means of the patient will permit, to advise the procurement and use of three distinctive trusses: one, intended for comfort, strength, and durability, for day use; another, equally serviceable in other respects and impervious to water, for bathing-use; the last, for comfort and security during the hours of rest.

[1] Read at the meeting of the Medical Association of the State of New York.

The advantages arising from this course are obvious, and too, it is equally obvious that if due care be not exercised in changing these trusses, the anticipated benefits from their use cannot occur. The establishment of the habit of assuming the recumbent position while making the interchange, is the only simple and safe method of procedure.

The manner in which cure is accomplished by a truss is not as yet thoroughly agreed upon. It is, however, a most important matter to be decided, as bearing on the proper mechanism of the truss itself. Do trusses cure hernia by establishing adhesive inflammation between the serous surfaces of the sac? or by retaining the viscera in the normal position, thereby permitting the displaced and stretched tissues to resume, as far as possible, the normal relations with each other? or, are both of these influences active in the cure? In my judgment the cures are rare where each of these influences plays an equal part in the cure. It is not my belief that adhesive processes are often excited within the sac by a hernial appliance. While it is no doubt true that in exceptional instances, by reason of the vigor of the appliance or peculiarities of the patient, adhesion may be effected, still a method or means directly intended to accomplish this indication would "make the treatment worse than the disease."

The occlusion of the sac appears to me to be due to contraction of that structure—a contraction dependent on the normal resiliency of it, aided by the friendly pressure of the contiguous surrounding tissues, caused by their return to the previously normal position. This contraction is of a uniform character at all aspects of the sac, as is indicated by the cord-like appearance of its remnant. If the obliteration of the sac were due to inflammatory adhesion incited by a peculiar variety of truss, then, indeed, would the local symptoms incident to such a process and the outlines of the occluded sac point to this change as the means of cure. I believe it is not too much to say that the tissue composing the sac, and also the tissues *around* the entire sac, will return to substantially their normal dimensions and relations when the distending and disturbing influences that have caused the change in them are long removed. If this be true, then the theoretical construction of a truss becomes quite a simple matter. The implement holding the pad in position should be elastic, and should exercise a degree of pressure sufficient to hold the truss in proper position, and at the same time exert enough additional force on the pad to prevent escape of the viscus. The pad should be of such a size and shape that, while the force from it does not tend to separate the point of exit of the viscus, still it will prevent the insidious entry into it of the intestines or omentum for even a short distance. In other words, the pad should be slightly convex, and large enough to exert pressure to some little distance beyond the border of the rupture. It should be hard, because a hard substance only will maintain the necessary relations just described. If it were soft, then the inequality of the resistance at the face of the pad, due to the existence of the separated and stretched tissues of the abdominal wall, would permit an inequality of the surface of the pad that would interfere with the return of the abdominal wall fibres to the normal relations. Furthermore, soft pads are less cleanly and less durable than the hard, consequently more irritating and expensive.

It seems to me to be entirely proper to consider the effect on the contents of a hernial protrusion exercised by their continuous retention within the normal cavity. It is a fact that cannot be gainsaid, that the long-continued existence of omentum, mesentery, and intestine, even in a gradually enlarging hernial sac, causes stretching and a more or less elongation of the omentum and the mesentery, and possibly of the intestine itself. The elongation of the omentum, and of a limited portion of the mesentery, is surely familiar to surgeons who have had the opportunity to study the characteristic appearance of the contents of hernial sacs, in connection especially with the attempted attainment of cure through radical means. It follows, naturally, if these tissues be retained within the abdominal cavity, that they, too, will again resume the normal proportions to a degree, at least, that entitles the hernial appliance to some favorable consideration in connection with the change.

The mechanical treatment of irreducible hernia introduces two additional aims, viz., support and protection of the protrusion. The protrusion should be so supported as to prevent further increase in the size of the protrusion itself, and also further increase in the area of the aperture of escape through the abdominal wall. A moderate upward traction on the protrusion is sufficient to neutralize the influences of gravity and other natural forces on it, and, in addition, to hold it gently against the abdominal wall in the course of the line of displacement. This condition of hernia ought always to be so protected as to obviate the dangers that ensue from the bad effects of traumatism. Neither time nor propriety will permit me to speak of the forms of trusses in the market. The medical man himself must judge between them, or from his inner consciousness evolve still another mechanism that equals or surpasses those already known. I will, however, submit the following conclusions to your consideration:

1. No form of truss yet constructed can be relied upon to cure any variety of simply reducible hernia.

2. The manner of the production of hernia, and that of its so-called cure by mechanical appliances, are such that cure by mechanical appliances, alone, need not be expected now, or hereafter.

3. Practical relief from the annoyance of a hernial protrusion may be had by the use of hernial appliances, which, however, ought always to be worn during all unusual physical efforts.

4. The so-called cures from hernial appliances are dependent on the restoration of displaced tissues to the normal position, and to obliteration due to natural resiliency of tissues; not, as is often claimed, to the inflammatory adhesion of serous surfaces, caused by special mechanical effects.

5. The hard, slightly convex pad, with the elastic steel spring attached, constitute the principal parts of the most philosophical, comfortable, cleanly, and durable of hernial appliances.

6. Suspension, elevation, and protection of irreducible hernial protrusions, are the main indications for this mechanical treatment.

Not long since, Mr. Heaton, of Boston, employed and recommended a method of treatment for the cure of reducible herniæ, which seemed, at that time, to offer to the afflicted of this condition the same ecstatic hope of immunity from it that the "Elixir" of Brown-Séquard incited in the credulous minds of frisky, though worthy, persons who had passed the "Rubicon" of life. Unhappily, however, for the latter class, the percentage of cure bids fair to be far less than that claimed for the former. I, myself, have had no experience with the "injection method," and do not now contemplate circumstances that will cause me to adopt this method of treatment, except perhaps in the young, and in cases of incipient herniæ, when other methods are not deemed advisable. However, there are with us to-day those who have tried the method effectually, and from them it is more befitting that statements should be received as to the efficiency of this method, than from one who can counsel only with theory and the lack of experience. It is, at all events, certain that a more effective method of radical cure is to be found in connection with the various operative procedures of the present day, than from the method by injection.

This leads to the inquiry, "Which is the best method of treatment for the radical cure, the 'open' or 'unopen' method?" I know of no better way of determining as to the relative merits of any special method of cure of any special condition, than that of inquiring at once as to the indications to be met, and as to whether or not this or

that special method complies the most fully with the natural demands for a cure. Let us take, as an illustration, a complete, simple, reducible, indirect inguinal hernia, and inquire as to the physical status of the affliction. 1. We find the internal ring dilated to admit the escape of the viscus; 2, the peritoneum is elongated by stretching and growth to form the sac; 3, the omentum, the mesentery, and perhaps the intestine, are elongated by the continued traction incident to their escape. The internal ring of fascia, and the corresponding peritoneum, are the first obstacles to the escape. When the viscus once enters the inguinal canal, the descent is not opposed by other than the tense elongating and enlarging peritoneal sac, the connective tissue in the inguinal canal, and the passive and varying pressure of the aponeurosis of the external oblique muscle, aided, perhaps, by the retentive influence of the elongating omental and mesenteric tissues. When once well in the inguinal canal, but little else obstructs the descent except the peritoneum composing the sac, and the lax fasciæ and integument of the abdomen. It therefore appears that the most substantial obstacle to the escape of hernia exists at the internal ring, and that when this is overcome, the formation of a complete hernia is merely a matter of time, facts which are confirmed by the clinical histories of cases of this form of hernia. From these statements it appears that the chief aim for the accomplishment of a radical cure must consist in so strengthening the internal ring and contiguous parts, that escape of intestine is both opposed and defeated. Now, which of the two methods just cited, the "open" or the "non-open" method, better strengthens the internal ring? The method of Macewen is, it seems to me, as good an example of the "non-open" method of treatment as can be selected. At least it is employed most frequently, is most strenuously defended, and best understood of the "non-open" methods. The method of Macewen occludes the peritoneal opening and strengthens the peritoneum at the internal ring, first by somewhat passive, afterward adhesive closure of the neck of the sac; also by elevating the serous membrane at this point, or "bossing" it, as it is often called, and by diminishing the capacity of the inguinal canal at the lower portion by the approximation of the conjoined tendon and the external pillar. The "bossing" is occasioned by confining the "ruffled" sac between the peritoneum and the fasciæ at this point. The occlusion of the peritoneal opening presumptively converts the peritoneum at this point into a nearly continuously smooth surface, when taken in connection with the contiguous peritoneum; while the "bossing" is supposed to elevate the peritoneum at the internal ring somewhat, to which elevation is assigned the functions of fortifying against and turning aside the internal visceral pressure at this, the weakened point. Assuming that all takes place that has just been described, we can add still further support by including the strength of the recently divided abdominal tissues, united as they are by the sought-for primary union. That it is reasonable to assert that closure of the neck of the sac does do it, as has just been stated, there can be no consistent doubt; but that the ruffling and placing of the sac itself, as is practised in this method, secures the "bossing" in many cases, is open to grave doubts. I am not aware that the occurrence of "bossing" has been actually demonstrated, but I am reliably informed that the reverse of the proposition has been noticed, under circumstances calculated to demonstrate it. It is difficult, indeed, to understand how the "bossing" can be maintained, even if it had occurred at the outset, when the external support to the internal pressure at this point is much lessened from the normal by the absence of, and by the weakened and elongated state of, the usual supporting tissues.

So much for the physical state of the "non-open" method. Let us now conduct a similar comparison in connection with the "open" method. In this method the neck of the sac is closed by a ligature. The sac is then cut off, aponeurosis of the external oblique slit up to opposite the internal ring, and the entire wound is caused to heal by granulation, care being taken to so treat the wound as to cause the cicatrix to reach up to and support the peritoneum at and about the point of ligaturing, which is the weakest place. Other stitches are taken to modify the shape and size of the scar, but the grand *finale* is this; with honors easy between the methods, so far as peritoneal surfaces are concerned, the peritoneal structure of the latter is supported and fortified by a cicatrix, which occupies the inguinal canal, *and which it is thought will prevent the further escape of hernia, so long as the cicatricial tissue continues to exercise the peculiarities characteristic of its nature.* The integument and fasciæ, too, are involved in this scar. In the "non-open" method the degree of the resisting influence exercised by the reunited tissues is also somewhat problematical, for the tissues, when healed by primary union, are capable of withstanding but little, if any, greater force than when in the normal state. The comparative resistance of normal tissue with that of cicatricial tissue, is easily understood when the latter is noticed so frequently to draw the former toward itself, with the same grim certainty that the unsuspecting mariner is said to have approached the traditional maelstrom. My experience with the "non-open" method is limited to nineteen cases, but I regret to be unable to state the results after a period of sufficient length (three years) to enable me to form more than an approximate estimate of the worth of the method from my own experience. The majority of these (eleven) were hospital cases, all of which passed from my observation in from four to six months. Of the remainder, I have no reliable knowledge, except in one instance of two years' standing which is *still* cured. Suffice it to say, however, that so long as they were kept under my observation, no return was noticed except in one—a hospital case—and this was within four months after operation. As to the "open" method, my experience is limited to five cases,[1] all but one of which have been performed during the last year. In the winter of 1887, in a clinic given at Bellevue Hospital, I treated a case of hernia for radical cure by the open method, in all practical respects. The wound was packed with gauze, but not with the special care and precision advised by Dr. McBurney. The healing occupied about six weeks, and when the patient was last heard from, one year after, he was still in a sound condition.

I cannot close this portion of the subject without calling to your attention a somewhat newer method of operating that I have practised on three distinct occasions. It certainly has some features that commend it, and, believe me, neither of these has to do with the fact that the method was devised, so far as I know, by myself. It is performed by weaving the sac, after separation, and ligaturing its neck with catgut into the pillars of the ring in the following manner: Fig. 1 shows the isolated sac, with the neck A tied (see foot-note on page 508), also the pillars of the ring slit for the purpose of weaving. Fig. 2 shows the sac carried upward beneath the inner pillar, and through the upper slit. Fig. 3 shows the sac carried downward through the slit nearest the border of the inner pillar, thence downward beneath the outer pillar of the ring to and forward through the lower slit of this pillar. Fig. 4 shows the sac passing upward through the slit nearest to the margin of the external pillar, and finally, if long enough, upward beneath the free margin of the inner pillar again. The borders of the pillars are then approximated by making tension of the sac, and the whole mass is finally quilted together with deep stitches of catgut, leaving sufficient room, however, for the passage of the cord (Fig. 5). The external wound was closed in each instance, and primary union followed without an unfavorable symptom. One of these cases was a female with a large, direct, painful inguinal hernia, which could not be retained in place by mechanical means, and the patient

[1] Since the writing of this paper, one of this number, operated on four months before, has been reported to me as showing evidences of return.

could secure comfort only by continuously assuming the recumbent posture. At the end of four weeks she was allowed to go about, and six months from this time, when last seen, was still in sound condition. In the second case the hernia returned six months after operation, during a severe attack of whooping-cough. The third case

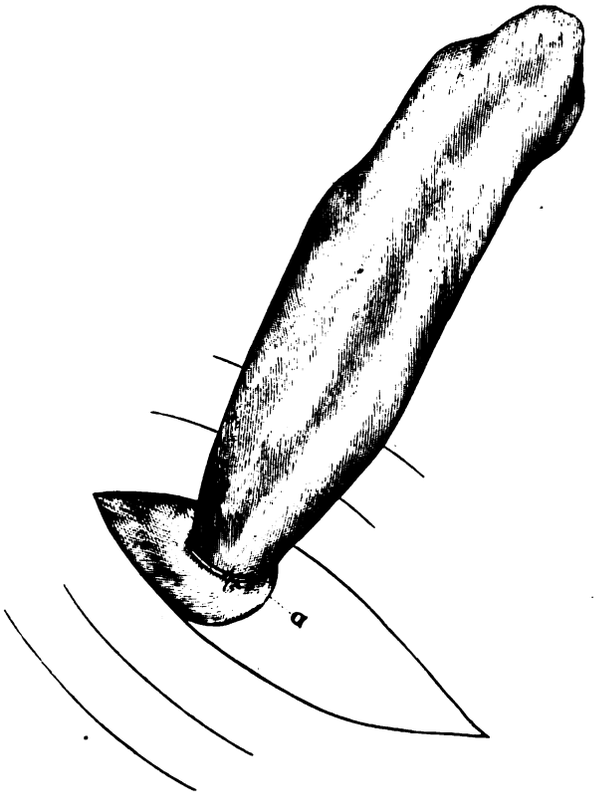

FIG. 1.—The Isolated Sac.

disappeared from observation entirely, as soon as allowed to leave the hospital. This method closes the neck of the sac, the same as the others; but, unlike the others, fills the inguinal canal with normal serous tissue, which is so placed as to support the peritoneum and fasciæ extensively at the weakest part. It is possible that still greater firmness can be secured if the wound be treated openly after the weaving and quilting processes are completed. In one of these cases the fasciæ in contact with the peritoneal sac were not disturbed, but were woven in as if peritoneum alone were present. This modification introduces a larger amount of tissue into the canal, and correspondingly increases the strength of the region, and likewise obviates any impairment of the nutrition of the sac that might arise from the removal of the fasciæ from it. It has been assumed that the ligaturing of the neck of the sac will cause the sac to slough, especially in old persons. In one of the cases operated on by myself, the patient was about sixty years of age, and, as already reported, a rapid and uncomplicated recovery supervened. However, if the danger of sloughing of the sac dependent on the ligaturing be the main objection to this method, then passive means of primary closure of the neck of the sac can be readily substituted for the ligature.[1] It is my opinion that this method cannot be employed indiscriminately as can the open method, since it frequently happens that the sac is illy developed, or so much damaged by isolation that it will be unwise to hope for particular benefit from the weaving process, even if it be possible to employ it; and, too, not infrequently the external pillar of the ring may be found to be so narrow and attenuated as to render its slitting impracticable. The following conclusions are submitted in connection with this phase of the subject.

1. That the open method of treatment is the most rational and the simplest method for the radical cure of hernia, provided the resulting cicatrix meets the expected requirements; consequently, the additional time required for treatment by the open method will be time well employed, if the cure resulting from this method should offer greater immunity from return of hernia than does that of any other method of treatment. 2. That the best sources from which to judge of the absolute and comparative results of the methods of radical cure are afforded by infirmaries for the ruptured, where the unfortunate persons go finally for relief, as a last resort. 3. That failure of the open method to cure, leaves the patient less amenable to the beneficial effects of a truss, and to subsequent radical treatment, than a failure from the non-open method, by the substitution of cicatricial for normal tissue; therefore, the percentage of primary cures from the open method should much exceed those of other methods, to insure the final benefit of the patient. 4. That the interweaving of the sac with the pillars of the ring, followed by open or closed treatment of the wound, will afford in many cases equal, and even greater, security than by any other method of treatment.

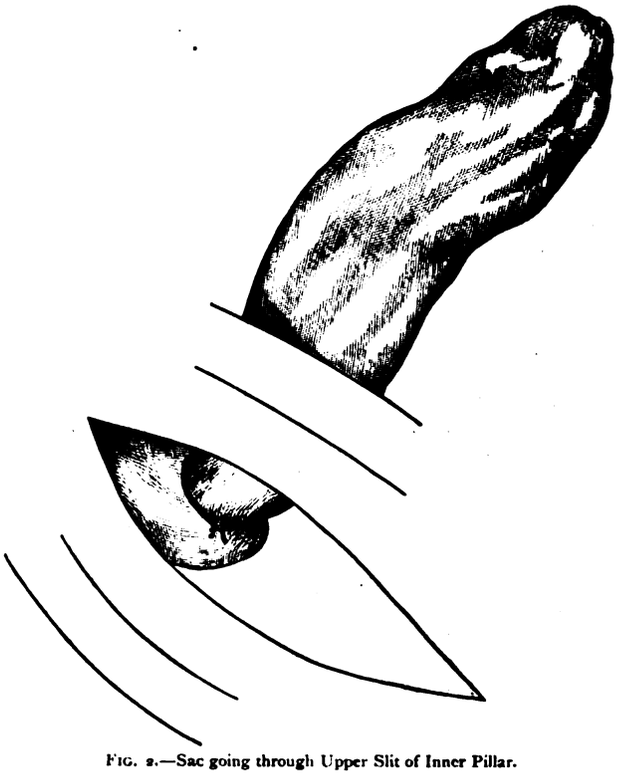

FIG. 2.—Sac going through Upper Slit of Inner Pillar.

The "medicinal and manipulative measures" of "palliative character" employed for "strangulated hernia," and the "reliance" placed in them, will be governed

[1] Since the presentation of this paper, I have had an experience which has caused me to advise against one step of the operation—ligaturing the neck of the sac. In a clinic given at Bellevue Hospital but a few days since, this method of treatment for radical cure was practised on a patient aged fifty-two. Four days after the operation a temperature of 102° caused an examination of the wound to be made. The superficial tissues had healed perfectly, but a limited separation of them, made for the purpose of examining the condition of the interwoven sac, disclosed the fact that limited portions of the sac were undergoing inoffensive disintegration. It has frequently been my practice to ligature the neck of the sac, before ruffling and depositing it, after the method of Macewen, and never before have symptoms arisen that were suggestive even of the idea of a similar unfavorable result. However, it is proper to say in this connection, that since the avowal of the unfavorable course in this case, others of a similar nature, in connection with a different method of operation in the practice of the Hospital, have been announced. It is now my intent[illegible]oced- omit ligaturing the neck of the sac, and to employ instead[illegible] by injec- passive means of closure.

At the next opportunity I shall scrape the inner surface of the sac slightly with a knife, and then pass a catgut lig[illegible] best method and around both walls of the sac at the middle of the the abdominal peritoneum, so as to include in the gra[illegible] or 'unopen' ture a portion—say one-fourth of an inch in width. [illegible]rmining as to

The ligaturing of this portion will prevent the entran[illegible] cure of any into the neck, without impairing the nutrition of the sa[illegible] closure of the neck has taken place under the pressu[illegible]nce as to the ings. [illegible]r not this or

largely by the experience of the medical attendant; by the surgical atmosphere in which he moves; by the means of carrying into effect the measures which he deems best for the patient; and, too, they will be modified not a little by the predilections of the patient and of the friends. The medical measures that quiet pain the easiest and quickest, and cause complete relaxation of the tissues, represent the palliative remedies to be employed. The measures that favor most the influence of the force of gravity on the protrusion, with or without the use of taxis, are together the palliative manipulative measures of standard reliability. Morphia injections, hot-water baths, with elevation of the part bearing the hernial protrusion, are

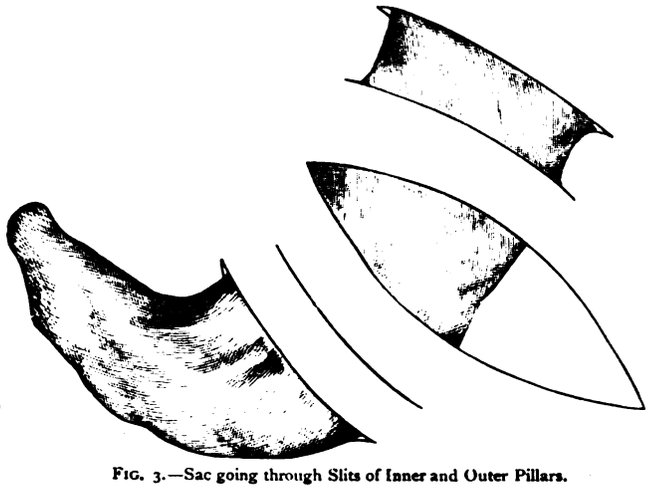

FIG. 3.—Sac going through Slits of Inner and Outer Pillars.

the best and most available means at the command of the medical attendant. If these be combined at once with well-directed and moderate taxis, a successful return of the viscus may be prognosticated under ordinary circumstances. If these means fail, and the local or constitutional symptoms of strangulation continue, then taxis should be tried again briefly, under complete anæsthesia, and, if not successful, herniotomy should follow at once. Too long, too frequent, and too forcible taxis are the ruling tendencies outside the hospital influences. Taxis ought not to be employed continuously for longer than a quarter of an hour. If it be properly directed, this is sufficient time in which to safely effect a reduction of the

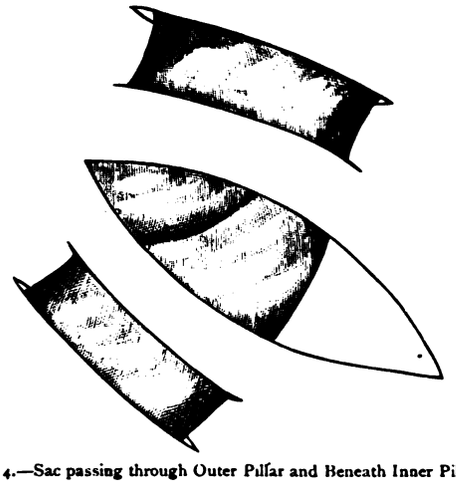

FIG. 4.—Sac passing through Outer Pillar and Beneath Inner Pillars.

gut; if improperly directed, then even *this* is much too long a time. The frequent employment of taxis in a single case arises from the unwise practice, that often inspires each medical man who comes in contact with the patient, to attempt the reduction. The majority make the attempt from proper motives; a few from vain and selfish ones that too often prompt the effort only because others have failed. The latter are the "John Horners" of the case, who, although they may not "stick in a plum," try to "stick in" the viscus; and if successful, each will cry "What a brave boy am I." Too forcible taxis comes of inexperience, haste, and unwarranted energy. Inexperience as a cause will always exist, but haste and unwonted vigor need never be practised. In view of the general knowledge of antiseptics in surgery, and of the results of their use, and also of the immense advantage to the patient from a radical cure, there is little ultimate benefit that can come to a patient now from even the wise and successful employment of taxis. However, it is not my intention to advocate the abolition of taxis; there is nothing so practical that can take its place. The ablest surgeon, the humblest physician, and the suffering patient, each employ taxis at the onset of the case, and not infrequently the self-experienced and self-educated patient employs it even more successfully than either of the others. It is the *abuse*, not the *use*, of taxis that demands condemnation. The medical attendants of hernial unfortunates should employ taxis when required, and should know how to do it properly in all respects. There are far greater numbers of medical men who can perform taxis successfully, than who can operate properly on strangulated hernia. Improperly performed taxis, when employed as cases arise, is not as fatal a procedure as inexperienced, bungling herniotomy under like circumstances. It is well to remember that, however confident the surgeon may be of the proper course to be pursued in a special case, that the patient and the friends may differ from him in some important respects. They will

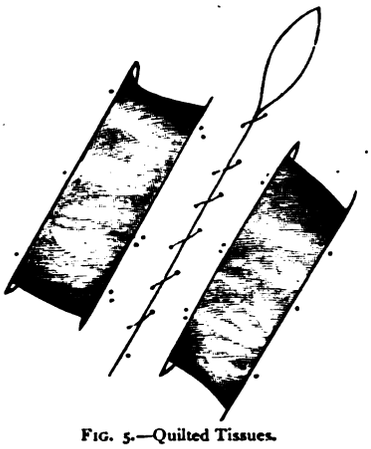

FIG. 5.—Quilted Tissues.

often oppose operative measures, because patients of whom they have known have died after the performance of them, and also because persons have recovered without them, and, too, in the face of the positive assertion of the surgeon that life can be saved only by operation. In such instances as these, one has but to state firmly, yet respectfully, his convictions of the case, and if unheeded, then decline to assume a responsibility which he himself can have no voice in creating. Your attention is invited to the following conclusions regarding this part of the discussion:

1. The abuse, not the use, of taxis constitutes an evil against which all surgeons should protest.

2. That a quarter of an hour of well-directed and continuously applied taxis is a rational procedure; longer than this is unnecessary, therefore unwise and harmful.

3. That repeated attempts at reduction on the part of different persons is pernicious, therefore dangerous and destructive.

4. That the present status of modern operative surgery has reduced the successful employment of taxis to the position of rendering but little practical benefit to the patient, except in special cases.

The rigid enforcement of antiseptic principles should be adhered to in all cases of hernial surgery. The antiseptic technique is as essential in successful radical cure operations, as in herniotomy itself. Hours can now be consumed in writing numberless pages on the "best technique applicable to an operation for strangulation hernia," and, at the end of the time little more will be said than ought now to be well understood by all such as may be

called on to operate for relief from this physical calamity. I will not, therefore, take the time of the Association by dwelling on the details of the line of incision, division of layers, identification of the sac, location and division of the construction, etc. It is my belief, however, that the surgeon who now neglects to perform an operation for a radical cure, as an addendum of herniotomy, falls short of his duty of consulting the best future welfare of the patient, provided, of course, that the immediate condition of the patient and of the tissues will permit. The question as between the selection of the open or non-open method in these cases, is largely a matter of expediency, in which the patient and friends should be consulted at the onset. If the time at the patient's command be short, and the condition of the tissues be favorable for it, then the non-open method should be selected. If, however, the final benefit to the patient alone be the only matter for consideration, then it is hoped that the open method may prove more highly commendable. The following conclusion is submitted:

That, all things being equal, radical cure should be practised as an addendum to herniotomy.

It happens occasionally that gangrene of the contents, or even of the sac itself, complicates strangulation. This is a complication of vital importance to the patient in a literal, and to the surgeon in a professional, sense. The proper treatment of such cases calls for as great display of skill and judgment on the part of the surgeon as is required for the treatment of almost any other surgical condition. The treatment of this complication should be divided into two classes, the *preventive* and the *remedial* treatment. The preventive treatment consists in an early reduction by taxis or by other means; or, failing in reduction, a prompt operation. The extremes of time after strangulation, before gangrene occurs, can never be accurately known, nor is it wise that these periods should even be approximately known, since it is unwise and dangerous to allow the question of the length of time of the existence of strangulation, as bearing on the occurrence of gangrene, to exercise any special influence on the operative judgment of the surgeon, since the existence of gangrene cannot be usually determined until after exposure of the contents of the sac by operation. The waste of important time in either nursing or considering hair-splitting theories, or in idle and useless prognostication, is evidence of the fact that much learning may become more dangerous even than a little.

The remedial treatment applies to the question, "What shall be done if gangrene have occurred?" If the sac alone be gangrenous—which is improbable—the gangrenous portions should be removed, the contents of the sac returned, the neck of the sac closed, superfluous portions of the sac cut off, and then radical cure should be sought for under the open method of treatment. If the intestine be gangrenous, the surgeon will then be obliged to entertain the propriety of practising one of the three following plans: 1, Of leaving the gangrenous intestine alone and relying on nature to form an artificial anus; 2, of the removal of the gangrenous portion and the stitching of the gut to the wound (if the constriction have already been divided), thus forming an artificial anus; 3, of excision of the gangrenous portion, immediate union of the extremities by sewing, and the return of the intestine to the abdominal cavity.

Which one of these plans should be adopted will depend largely on the following considerations: 1, The physical condition of the patient; 2, the physical condition of the wall of the intestine; 3, the portion of the intestinal tract involved by the gangrene; 4, the surgeon's available knowledge of the technique of the requirements of the case.

It is not, in my judgment, ever advisable to allow nature an unaided course in the matter. The sooner the tension within the intestine is relieved by causing a free escape of the obstructed contents, the sooner relief will be had from the distressing symptoms of strangulation. It is not difficult to understand that the additional time required to bring relief through nature's efforts alone might be the determining cause of the death of the patient; and, too, the early relief of the intestine from the effects of internal pressure and extreme vascular plethora, will reduce the extent of the sloughing to a minimum. There appears to me to be no doubt of the fact that, after carefully protecting the wound from contact with the intestinal contents, the gangrenous intestine ought to be incised sufficiently to relieve its fecal and vascular plethora. I deem it unwise to divide the constriction before incision and depletion of the intestine, except the constriction be thought to be too narrow to permit the escape of the contents without division—a degree of closure that must be rare indeed. The reasons for this opinion are: 1, Such a course may permit the intestine to elude the grasp of the surgeon and escape into the abdominal cavity, with obviously fatal results; 2, after depletion of the intestine, the division of the constriction may be found to be unnecessary, and even unwise, if the establishment of a temporary artificial anus be contemplated. However, if, after depletion, the extent of the gangrenous portion of the intestine appears to be limited in part or entirely by the seat of the constriction, or the amount of non-gangrenous intestine outside of the seat of stricture be too small to meet the requirements of a properly formed artificial anus, then the constriction should be carefully divided, and the intestine drawn down sufficiently, at least, to bring to view a healthy, complete, intestinal circumference, which should then be stitched to the border of the wound with silk, or otherwise retained if immediate or remote enterorrhaphy be contemplated. If, after the depletion of the intestine, a sufficient amount of non-gangrenous gut remain external to the constriction to meet the further demands of the case, then the constriction need not be divided, provided, of course, that the internal pressure from intestinal contents has been entirely relieved. The means to be adopted by the surgeon to determine the existence of gangrene of the gut are standard matters in almost innumerable publications. I can add nothing to the list of stereotyped measures so long employed for this purpose. After exposure of the gut, if the question arise as to whether or not gangrene may supervene, care should be taken to completely relieve all constriction of the gut, and also to retain it *in situ* until this element of the prognosis is determined; then the degree and extent of the gangrene will control the subsequent action of the surgeon. If it be of so small an area that the removal and the repair do not reduce the calibre of the intestine to less than two-thirds the normal diameter, the gangrenous area should be removed, the opening closed by sewing, and the intestine returned to the abdominal cavity. It is important to remember, however, that an impairment of the mesenteric border of the intestine should not be thus treated; this condition calls for excision of intestine to the extent of the mesenteric impairment, otherwise gangrene of the intestine may ensue to a similar extent. If gangrene of the gut be too extensive to admit of a simple method of repair, what then should be done? Shall an artificial anus be established to be cured by a subsequent operation, or shall the gangrenous intestine be excised at once, the extremities united, and the bowels returned to the normal cavity? If the condition of the patient be such as to warrant the belief that an operation of an hour and a half or two hours' duration may be performed with reasonable safety, the intestine should receive a radical and permanent treatment at once, and be returned into the abdominal cavity.

If the character of the intestinal discharges, the [illegible] tion of the protrusion, and the anatomical char[illegible] of the bowel, warrant the belief that the jeju[illegible] volved, then radical operation should be p[illegible] once, even at great risk to the patient, other[illegible] anition will ensue, which, if it do not destro[illegible] in a few days, will so quickly enfeeble him [illegible] the possibility of a favorable result from a [illegible]

tion. As an illustration of this, Riedel reports a case where the opening into the intestine was located about half-way between the pyloric extremity of the stomach and the cæcum (eleven feet), in which rapid inanition ensued, and at the end of twelve days radical operation was performed as a last resort, and without success. It is wise in this connection to remember that the jejunum is commonly located in the umbilical and left iliac regions of the body.

The condition of the walls of the gut, adjacent to the opening in it, does not exercise so very important influence on the chance of the immediate radical, or the temporary anal, operation for gangrene, because in either instance sufficient intestine can be readily withdrawn to secure sound and non-congested tissues for sewing. However, other things being equal, it is better to restrict the extent of the excision of the intestine to the narrowest practical limits, for, the longer the piece removed, the longer will be the time employed in the operation. The congested state of the intestine should not cause delay in the operation if the intestine be involved in the upper two-thirds, since the danger of inanition due to delay will be greater to the patient than the sacrifice of all the congested intestine contiguous to the opening. At all events, the sewing should be done in the perfectly normal intestinal tissues, if the best results are to be expected. It is proper to say at this time that the removal by excision of four or five feet of small intestine need not cause undue apprehension as to the possibility of inanition of the patient. Koeberlé is reported to have excised nearly seven feet without causing a resulting appreciable change in the nutrition of the patient.

In the operative treatment of gangrene of the intestine by the radical method, rapidity, thorough antisepsis, and complete familiarity with the technique of the steps of enterorrhaphy are of most vital importance; so important in fact, that the operation should not be attempted except by the best skill at command. It is far better for a patient that an artificial anus be made, even with unfavorable prospects, than that immediate radical measures be attempted by those not familiar with their surgical technique, since it may soon be possible to secure the necessary skill. It will be noticed that I have not employed statistics, not described the minute details of measures on the knowledge of which strong insistance has been made. The reasons for this course are twofold: 1, Because time would not permit it; 2, because these facts could be more appropriately considered in connection with the special parts of the discussion allotted to others. The following conclusions appear to me to be properly deduced from the preceding statements:

1. When gangrene of the intestine has taken place and the condition of the patient will permit, intestinal repair should be practised at once, and the gut returned to the abdominal cavity.

2. When gangrene has occurred, presumptively involving a portion of the upper two-thirds of the intestine, intestinal repair should be practised at once, and the gut returned to the abdominal cavity, even if the immediate result of the operation be somewhat doubtful.

3. When gangrene has occurred and the condition of the patient will not permit immediate operation, a temporary artificial anus should be formed.

4. It is better to form an artificial anus, under all circumstances, when the medical attendants are not familiar with the details of intestinal surgery.

5. Division of the constriction is not always necessary, and is often unwise when the formation of an artificial anus is contemplated.

---

AN INSPECTION OF FOOD IN THE RUSSIAN ARMY.—The medical authorities of the Russian Ministry of War have decided to establish ambulatory laboratories in connection with each army corps, in order that a strict investigation may be made into the quality of the food supplied by the commissariat.

## ON THE PATHOLOGY AND TREATMENT OF INTRA-PELVIC INFLAMMATIONS.[1]

BY L. S. McMURTRY, M.D.,

DANVILLE, KY.,

FELLOW OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS; FELLOW OF THE OBSTETRICAL SOCIETY OF EDINBURGH, ETC.

INTRA-PELVIC inflammations, with their sequelæ, compose the most common conditions with which the gynecologist has to deal. In the entire compass of medical science and practice no subject has been more misunderstood, and none more erroneously interpreted.

Thirty years ago Bernutz and Goupil, after careful clinical and post-mortem investigations, clearly described the true pathology of pelvic inflammations, but it has only been since operative surgery has opened up the peritoneal cavity to daily exploration that their researches have been appreciated and accepted. Even at this advanced period, many of our prominent teachers and authors classify intra-pelvic inflammations under two heads—*para-metritis*, and *peri-metritis*—with treatment adapted accordingly. Modern investigation has swept this classification aside, confirmed the truth and accuracy of Bernutz's researches, and demonstrated the relation of diseased states of the ovaries and Fallopian tubes, together with puerperal, specific, and other infections, to pelvic inflammations.

It is not my purpose to review before this audience the anatomical relations and histology of the pelvic organs, a task altogether superfluous; nor will I, except in the most casual way, touch upon the vast literature of pelvic inflammations. It seems to me most profitable at this time to treat the subject from the pathological and clinical standpoint.

M. Bernutz made a most happy comparison between inflammation within the pelvis and the same process within the chest. Skene and other modern writers have utilized the same analogy to describe and illustrate the pathology of intra-pelvic inflammation. In both thoracic and pelvic inflammation we have the croupous and catarrhal processes. We have peritonitis and parenchymatous inflammation on the one hand, while we find pleuritis and parenchymatous inflammation on the other. In pelvic inflammations we have recovery by resolution just as in pleuro-pneumonia, leaving adhesions and bands in the one cavity as in the other. When the inflammatory process so interferes with nutrition as to destroy vitality, we have pelvic abscess in the one site and pyothorax in the other. We find the bacilli of tubercle invading the pelvic serous membrane and contained organs, just as in the pleura and lungs. A mucous surface furnishes access for infection in both cavities. M. Bernutz further states that uterine pathology is as certainly subordinate to a thorough acquaintance with pelvic peritonitis, as pulmonary diseases have been to a complete knowledge of pleuritis made possible by the discovery of auscultation. In the light of knowledge recently established, this last statement shows how thorough and profound were the researches of these eminent clinicians and pathologists, MM. Bernutz and Goupil.

Permit me to continue in the lines indicated by Bernutz once again. After discussing the theory of pelvic inflammation promulgated by M. Nonat—essentially that of pelvic cellulitis, which until recently held full sway in the practice of modern gynecology—he says: "For some time I had no idea that the view propounded by M. Nonat was a mere hypothesis which rested on no post-mortem evidence. And it was not till after the unfortunately fatal termination of two cases that I was able to prove incontestably, that the peri-uterine tumor which, during life, presented all the symptoms of the so-called peri-uterine phlegmons, was not situated in the cellular tissue at all. In the autopsies in question, the tumor, which even after death presented all the usual signs, was seen to be formed by the pelvic viscera being matted together by peritoneal ad-

[1] Read before the American Association of Obstetricians and Gynecologists, September 18, 1889.

hesion. . . . These researches, then, have led to the conclusion that inflammation of the pelvic peritoneum, which is the cause of the visceral adhesions, is a disease which is very commonly met with. . . . Lastly, I conclude that inflammation of the pelvic serous membrane is symptomatic, and that it is generally symptomatic of inflammation of the ovaries or Fallopian tubes. Thus great interest attaches to the study of this affection, and it is very important to thoroughly understand the symptoms, in order to describe satisfactorily the uterine, and more especially the tubo-ovarian, diseases which occasion it. . . . It follows from all this that, unless we get fatal cases to enable us to determine anatomically where the pelvic inflammation began, we cannot state positively whether it came from inflammation of the ovary or of the Fallopian tube; nor whether it was caused by the puerperal state, by blenorrhagia, scrofula, or any other malady. Thus we can only lay hold, as it were, of the two ends of the pathological problem, the primary disease and the serous inflammation—the intermediate gap we can only fill up after death."[1] Herein may be found the very essence of the most advanced pathological knowledge of the day concerning intra-pelvic inflammations, and it is surpassing strange that the researches of MM. Bernutz and Goupil lay before the profession for so many years like good seed upon sterile ground. It was only when the science and art of surgery made great strides forward, as illustrated in the perfected aseptic surgery of the day, that "the intermediate gap" which Bernutz could "only fill up after death" was filled up during the life of the patient. The researches of Bernutz and Goupil in this important field of pathology are complete, and constitute the basis of the pelvic surgery of the present time; their work is the first and greatest, a monument to the genius and patient industry of these faithful followers of science.

The points relating to the pathology of pelvic inflammations which have been established, the correctness of which I am fully convinced by my own clinical observation and experience, may be grouped in this manner:

1. Intra-pelvic inflammations cannot be properly classified as para-metritis and peri-metritis, inasmuch as inflammations of serous and cellular tissues cannot be separated clinically or histologically.

2. Peri-uterine phlegmon of Nonat (pelvic cellulitis of Emmet) is as rare as inflammation of the cellular tissue in other parts of the body.

3. Intra-pelvic inflammation is, as a rule, *peritonitis*, resulting from disease of the ovaries and Fallopian tubes, arising in puerperal or gonorrhœal infection, or the miscellaneous infections carried to the endometrium by unclean instruments, tents, or medicinal agents, or from traumatism.

4. Pelvic peritonitis is symptomatic, never idiopathic. Pelvic peritonitis presents every grade of severity. In some instances there is a mere inflammatory spot, giving rise to but little discomfort at the time and passing away without treatment, leaving a bare trace behind, often found post mortem. A higher grade is illustrated by those instances wherein the peritoneum exhibits subserous congestion, transudation of serum, and exudation of plastic material. In a more severe grade there is immense transudation of serum, which accumulates in the pouch of Douglas, corresponding to pleurisy with effusion. In a very high grade the entire pelvic peritoneum is involved, the several stages of the process—congestion and exudation—are followed by suppuration, an affection of fearful proportions, and unless treated surgically, going often to a fatal issue. The sequelæ of pelvic peritonitis depend upon the vitality of the individual, the grade of the inflammatory process, and the area involved. Where the surface is limited, or maybe quite extensive, recovery may take place by resolution and leave only slight adhesions behind. When the inflammation is higher and the exudate more extensive, layers and bands of false membrane remain, forming organized adhesions. The products of inflammation may be deposited over the uterus, ovaries, and broad ligaments, leaving these organs imbedded or entangled in a mass of adhesions. As time goes on the exudate passes through repeated stages of congestion into organized tissue, with constant tendency to contraction. Pressure upon the ovaries is followed by inflammation, degeneration, and atrophy of these organs. The fimbriated extremities of the Fallopian tubes are imprisoned and destroyed. At each recurring menstrual flux these bands are made tense by congestion, increased in thickness, and more thoroughly organized. In addition to the lesions entailed by pressure, the secretions are retained, and ovarian abscess and pyo-salpinx are common results. When the inflammation is very intense, involving subserous structures, the vitality of tissues is destroyed and one form of pelvic abscess is the result.

Although it is not contemplated to discuss the diagnosis and symptomatology of intra-pelvic inflammation in this paper, I must be permitted to dwell for a moment upon the clinical picture which corresponds to the lesions I have just described. A woman suffers an attack of gonorrhœa, often contracted innocently, and has a severe attack of pelvic peritonitis. Or she has an abortion, or labor at full term, and has the misfortune to become infected and peritonitis results. After a severe and protracted illness the acute symptoms pass away; in time she gets up and is congratulated by her friends upon her convalescence and recovery from so severe an illness. Time wears on with improvement in her general condition, but she maintains that she is not well. The menstrual periods are seasons of intense pain and distress, and usually opium is administered. By and by the family physician makes an examination, and my observation has been that he usually decides a malposition of the uterus to be the principal trouble, and inserts a pessary. The trouble persists, and pain is intensified by the pessary, which after a varying period has to be abandoned. The woman is an invalid. If well-to-do she spends the greater portion of her time in bed, drives out occasionally, and craves morphia, chloral, and other anodynes. She walks with a peculiar halting gait, has a pinched expression, and suffers from reflex nervous disturbances. She is treated with the hot vaginal douche, local applications to the cervix and vaginal vault, and is improved by none of them. About this time massage, rest in bed, milk diet, with varying and unsatisfactory results, will be invoked in her behalf, but nothing in the way of permanent relief results. She is a helpless invalid, and a great sufferer. The ultimate issue of the case may be one of three alternatives: either to hold out until the menopause, when physiological repose and atrophy may bring relief; to remain an invalid for years with opium and all the accompanying misery, ending probably in abscess; or to have the diseased and imprisoned organs, with their consequent histological changes, removed. I submit that the picture is a familiar one to those who see much of pelvic disorders. In connection with such a pathological state, we must not overlook the persistent influence of the menstrual congestion upon the growth and density of the organized exudate to which I have previously referred.

The treatment of intra-pelvic inflammations must depend upon the structures involved. The cardinal fact that pelvic peritonitis is always symptomatic, always the sequel and result of infection, must never be lost sight of in formulating any plan of treatment. Catarrhal inflammation of the endometrium may, by the ordinary process of continuity of surface, extend to the tubes and ovaries. Prolonged congestion and thickening of the mucous lining, with retained secretions, results in localized peritonitis.

Treatment by depletion, cleanliness, antisepsis, and drainage may arrest and limit the inflammatory process and induce a cure by resolution. The peritoneum is an immense lymph-sac, quick to open the avenues of microbic invasion. An untidy exploration with the uterine

[1] Clinical Memoirs on the Diseases of Women, New Sydenham Society, London, 1867, vol. ii., p. 5.

sound often conveys the infectious spark which spreads from the endometrium like fire on the prairie. Gonorrhœa is a disease leaving in women the formidable sequelæ of salpingitis, peritonitis, pyo-salpinx, ovarian abscess, and often general suppurative peritonitis. Labor and abortion are processes especially prone to admit infection, and unless rigid cleanliness is observed, are usually followed by varying grades of pelvic inflammation. Rest, the clean hot douche facilitating drainage, saline cathartics favoring revulsive drainage and depletion, are means of treatment which often arrest and limit the inflammatory process and lead to cure by resolution. To recount the various pathological states of the uterus, ovaries, and Fallopian tubes, with which general or localized pelvic peritonitis is associated, would of course greatly exceed the limits of this paper.

In consequence of the matting together of the pelvic organs by adhesive inflammation, the exact seat and starting-point of the inflammatory process cannot be decided by the ordinary means of pelvic exploration. Fortunately, the indications for operative interference are so unmistakable that such exactitude in diagnosis is not essential for proper treatment. The localized pain, the fixation of movable organs, the exudation, and, when pus has formed, the rigors, fever, and emaciation, are signs too positive to be overlooked by the experienced attendant. When the means that I have indicated fail to secure resolution, and septic symptoms present themselves, we may know that the only treatment is to open the abdomen, evacuate the pus, remove the inflammatory mass (usually Fallopian tube and ovary), cleanse the peritoneum, and establish drainage. Where the disease has gone on to suppuration, the surgeon has no option. The only course worthy of consideration is thorough removal of inflamed, suppurating, and degenerated ovaries and tubes, of which pelvic peritonitis is the result. Equally is it the surgeon's duty to operate in those cases in which the diseased tubes and ovaries, one or both, can be made out by the touch upon the side of the uterus, accompanied with pain and the familiar functional derangements incident to diseased states of the tubes and ovaries. I am presuming, of course, upon discriminating knowledge on the part of the physician. To operate early, before adhesions become organized and the inflammatory area extends, and before pus forms and the system is infected, simplifies the operation, enhances the patient's chances of recovery, and abbreviates suffering.[1] In illustration I may mention hydro-salpinx and hæmato-salpinx as prone to purulent change.

When bands of false membrane have imprisoned the Fallopian tubes and ovaries, with the consequent alterations of structure already described; when the tubes are in a state of constantly recurring inflammation, with functions destroyed and secretions retained; when the ovary has become cirrhotic or undergone caseous degeneration; when the patient is a miserable invalid and opium habitué; then these organs should be removed and the patient restored to health, home, and society. In cases of limited pelvic inflammation, careful discrimination is necessary in deciding upon operative treatment.

For accurate diagnosis an experienced tactile sense and repeated examination are required. Many cases of intra-pelvic inflammation of lesser grade are improved, and some few cases cured, by the hot douche, the application of iodine and glycerine, the supporting tampon, and rest; but the larger class of cases, in which the inflammatory process has been more active and extensive, are incurable without operative interference. Moreover, women dependent upon their own labor for a livelihood, and those of meagre pecuniary resources, are unable to indulge in months of palliative treatment for temporary relief. To those of us who have dealt with cases of long-standing pelvic inflammation at the operating-table, and shelled out diseased tubes and ovaries from a mass of organized exudate, the cures claimed for electricity in such cases are difficult to accept. When treated upon sound surgical principles, by abdominal section, the results are good, the cures permanent, and restoration complete.

[1] Operation by abdominal section should invariably be adopted in preference to puncture of Douglas' space through the vagina.

## BRIEF MEMORANDA IN PRACTICAL OTOLOGY.

By ALBERT H. BUCK, M.D.,

CLINICAL PROFESSOR OF THE DISEASES OF THE EAR, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; CONSULTING AURAL SURGEON, NEW YORK EYE AND EAR INFIRMARY.

AMONG the cases which I have seen in private practice during the past few weeks there have been two which seem to me to present features sufficiently interesting to warrant their publication in a medical journal.

A lady, about fifty years of age, and almost entirely deaf in her left ear, reported that she had suffered for a long series of years from an almost constant discharge from the right ear. At times this discharge had been so slight as to lead her to believe that it had ceased; in point of fact, however, it had simply at these periods become too scanty to actually flow out of the ear. The hearing had been variable; sometimes she could hear so well that nobody would suspect the existence of any deficiency in this respect, while at other times her deafness would be very marked, lasting sometimes for days together. Latterly there had been more discharge than usual, and the duration of the period of marked deafness had been unusually long. On one or two occasions, during this period, she had experienced a sensation as if some obstacle had been suddenly removed from the right ear—practically the only ear with which she can hear—and then, for a few minutes, she had been able to hear, as she thought, perfectly well. An examination with speculum and reflected light revealed the presence of a small quantity of muco-pus covering the apparently unbroken surface of a red and thickened membrana tympani. On closer scrutiny a barely recognizable irregularity of the surface was noted in the posterior superior quadrant. At this spot the tissues appeared to be more succulent than elsewhere on the surface of the membrane. In no other respect did this part of the membrane seem to differ from the surrounding parts. By manipulating the tissues at this suspicious spot with the end of the slender middle-ear probe it was readily ascertained that the membrana tympani was perforated at this point and that granulation-tissue filled the recess beyond, *i.e.*, the entrance to the mastoid antrum and the depression corresponding to the fenestra ovalis. By forcing a small pledget of cotton into this opening I was able to press back the granulation-tissue to such an extent that a visible recess or opening appeared where a moment before there was simply an irregular granulating surface. The moment I had withdrawn my probe, armed with a pledget of cotton, the patient exclaimed, "Now I hear your voice and the sounds in the street perfectly well!"

The therapeutic problem involved was simply this: The removal of the cushion-like mass of tissue which prevented outside sounds from making a sufficiently powerful impression upon the stirrup. As the granulation-tissue could not be isolated, and consequently could not advantageously be removed by means of Blake's fine wire snare, I was compelled to resort to the use of a caustic, viz., silver nitrate, in the form of a small bead of the pure salt fused upon the end of a slender middle-ear probe. Three such cauterizations were made, at intervals of about forty-eight hours, and then injections of a weak silver-nitrate solution (five grains to the ounce of water) were made on alternate days, through the opening in the membrana tympani, into the mastoid antrum; the glass middle-ear pipette being used for this purpose. By way of supplementary treatment the patient cleaned the canal thoroughly, three times a day, with tepid water introduced into the ear by means of an Angelo's ear-douche.

In the course of two weeks the inflamed mucous membrane of this part of the middle ear had so far recovered its natural healthy tone that all discharge had practically ceased, and the patient was once more able to hear well continuously.

The second case, of which I desire to give a brief account, occurred in the person of a physician residing in this city. He consulted me on account of a very unpleasant sense of fulness and pressure in the region of the right ear, associated with an increase of his more or less habitual naso-pharyngeal catarrh, and with very slight impairment of the hearing. These symptoms had troubled him for about two weeks. Examination with the speculum and reflected light revealed the existence of a noticeably sunken and slightly congested drum-membrane. The use of a Politzer's inflation apparatus afforded only momentary relief. The diagnosis was, clearly: Obstruction of the right Eustachian tube, due to catarrhal swelling of the mucous membrane of that region. The treatment consisted in painting the vault of the pharynx, and especially the vicinage of the right tubal orifice, three times a week, with a twenty-grain solution of silver nitrate; and at the same time the patient was advised to abstain from smoking tobacco during the course of the treatment. At the end of two weeks he reported that his right ear felt exactly as uncomfortable as it did before treatment was begun, and that, too, despite the fact that a very noticeable diminution had taken place in both the redness and the degree of swelling of the visible fauces. He called my attention, however, to one or two phenomena which he had observed, and which led him to think that a neurotic element played a part in his troublesome symptoms. For instance, he had observed that the pressure of the steel arm of his spectacles upon the skin of the right mastoid process greatly intensified the sense of fulness in the affected ear. There were other things still which, as he had discovered, would produce the same temporary aggravation of this sense of fulness, but I cannot just now recall them. The patient's own idea was that malarial poisoning—from which he had suffered to some extent during recent times—was at the bottom of these nervous phenomena, and in accordance with this idea he began taking ten grains of quinine daily, and continued to take the remedy in these doses until he experienced a slight ringing in the right ear. By this time he had taken ninety grains in all. The effect of the quinine was very marked. The sense of fulness and pressure rapidly grew less, and disappeared entirely on the fourth or fifth day. The sinking in of the membrana tympani became so slight that it could be barely recognized. Furthermore, the patient had lost all traces of the depressed state of mind which constituted one of the features of the disease in its earlier stage.

A few comments may not be out of place in connection with these brief histories.

In the first place, I may be permitted to remark, in connection with the case of otitis media purulenta, that simple inspection of the drum-membrane, no matter how brilliant the illumination of this region may be, cannot always suffice to furnish us with a true and complete pathological picture. Inspection conjoined with careful manipulation of the parts is absolutely essential, in certain cases, to the correct determination of the nature, location, and extent of the disease. In this particular instance, the undisturbed picture presented to the eye of the observer was thoroughly misleading.

The second thought suggested by the case under consideration is the fact that sudden and very marked changes in the power of hearing (in one ear) imply alterations in the mechanical relations of the stirrup. I am confident that alterations at the round window (*i.e.*, in or around the secondary tympanic membrane) influence the hearing power far less potently than do those at the oval window. A pad of granulation-tissue or of greatly hypertrophied mucous membrane is competent, in the absence of the anvil, to so greatly diminish the intensity of the sound-impulses which reach the stirrup that the corresponding ear can hear only the loudest tones. But if the anvil and the stirrup still retain their connections, the same mass of tissue will probably diminish the hearing-power only slightly. In the present case no trace of the long process of the anvil could be found, and the stirrup was therefore entirely shut off by the surrounding mass of soft tissue from the direct impact of waves of sound entering by way of the external auditory canal. There is another class of cases which in all essential features closely resemble the one described above, but in which the removal of the obstructions existing around the stirrup fails to establish that acuteness of hearing which from time to time so startles and delights the patient. How are we to interpret the marked spontaneous improvement which takes place in the hearing power in these cases? In my efforts to explain it I have assumed the momentary pressure of some moderately hard substance (like a flake of epidermis or a mass of hardened secretions) upon the head of the stirrup—in a word, the establishment, for a few moments, of a sort of artificial drum-membrane. Acting on this theory, I have applied all sorts of wooden, metal, and dried elder-pith contrivances in contact with the head of the stirrup, but I have never once succeeded in reproducing artificially one of these brief intervals of acute hearing.

In regard to the second case, I may remark that the part played by malaria in weakening the inhibitory power of the vaso-motor nerves supplying the mucous membrane of the nose, throat, and ear is something new to me. The discovery of this peculiar relationship, it has probably been remarked already by the reader, was made not by myself but by my patient. I have no doubt that many of my fellow-specialists have experienced the same difficulty in their own practice, viz., the tendency to give undue weight to the purely local causes of disease.

---

## WHY PHYSICIANS SHOULD CULTIVATE PHOTOGRAPHY.

By BOARDMAN REED, M.D.,

ATLANTIC CITY, N. J.

AMATEUR photography is just now much in vogue, and it is cultivated more by physicians than others. There are good reasons for this. The education of the medical man, if thorough as it should be, fits him well for the "black art." He is, of course, familiar with chemistry, and ought also to be conversant enough with physics and mathematics to master the intricacies of lenses and the calculation of their equivalent foci.

But even without going at all into the science of it, the busy doctor may find photography a useful help in his everyday work, as well as one of the best of all possible out-door recreations for his vacation season. Like gunning, it lures its votary out into the fields, along the hillsides, and by the running brooks. Unlike that rougher and more ancient sport, however, it does not lead him through thorny thickets, or, at unchristian hours, through tall, dew-laden grass and miasmatic swamps, thus risking an exchange of his dyspepsia for rheumatism and malaria; but rather tempts him to select for his outings the pleasantest parts of sunny days, and permits him to pick his way by unobjectionable paths to the most picturesque and romantic bits of scenery in his neighborhood. The exercise and zest are much the same; but, apart from the effects upon the health, the amateur photographer has usually something better to show for his day's tramp. Supposing that he has acquired a fair amount of skill, he will be sure of at least one or more pictures which may sometimes be really things of beauty, and will then be joys forever. The gunner, on the other hand, however experienced, may not find any game, or, finding it, may fail to hit it; and even when he is most successful the net results of his day's sport are promptly eaten, and thereafter exist in memory only.

Then there is the ethical side of the question—the im-

memorial tendency of hunters and anglers to stretch the truth, while photography conduces to literal exactitude in all respects—but the contrast need not be pursued further.

Turning now to the practical value of photography to the physician, there are good reasons why every one of us should own a camera and know how to use it. By means of the magnesium flash-powder and the extremely sensitive dry-plates now in use it is not difficult for any person, after a few hours' instruction, to make a passably good negative in an office either by day or night. In this way cases of facial paralysis, spinal curvature, hip-joint disease, and marked skin disease, or any form of bodily deformity can be easily photographed by an instantaneous process, and thus the best of all records be kept of them for future reference.

And for those who devote themselves largely to microscopy, photography opens up an almost boundless field, enabling them to fix in enduring forms the magnified representations of the specimens studied by them.

Moreover, lessons of value are to be learned from even the technique of photography. For example, plates that are exposed too long, as well as those exposed for too short a time, make weak, unsatisfactory negatives. In like manner we find that overfeeding as well as underfeeding may debilitate a patient, rendering him ultimately weak and unfit for severe exertion.

The writer feels himself deeply indebted to photography for one highly important lesson in hygiene, that is, the relative value of out-door sunshine as compared with the diffused light of an ordinary room. Most persons would say that the outside light is two or three times as strong as that within our houses. But the ratio of difference is vastly greater. Carefully prepared tables show that for a view at the sea-shore, comprising sea and sky mainly (with a lens and plate of a certain speed), an exposure of one-tenth of a second is sufficient. An open landscape away from the sea would, with the same lens, the same aperture, and the same plate, require one-third of a second. A fairly lighted interior would require two and one-half minutes, while a badly lighted interior—such as the rooms which most ladies prefer to occupy—would require half an hour to obtain an equally good picture. In other words, patients strolling on the sea-shore in sunny weather are in a light not two or three times, but eighteen thousand times, stronger than that in the ordinary shaded and curtained rooms of a city house; and the same patients walking along the sunny side of a street are receiving more than five-thousand times as much of the health-giving influence of light as they would receive in-doors in the usually heavily curtained rooms.

No wonder such miracles are wrought by sending our sickly human house-plants to the country or mountains, or to the sea-shore, where the stronger sunlight, the purer air, and the invigorating salt-water all combine to revivify the vital forces!

---

Cocaine Hallucinations.—MM. Magnan and Saury report three cases of hallucination due to the cocaine habit. One patient was always scraping his tongue, and thought he was extracting from it little black worms; another made his skin raw in the endeavor to draw out cholera microbes; and a third, a physician, is perpetually looking for cocaine crystals under his skin. Two patients suffered from epileptic attacks, and a third from cramps. It is important to notice that two of these patients were persons who had resorted to cocaine in the hope of being able to cure themselves thereby of the morphine habit, an expectation which had been disappointed. For more than a year they had daily injected from one to two grammes of cocaine under the skin, without, however, giving up the morphine injections, which were only reduced in quantity. The possibility of substituting cocainism in the endeavor to cure morphinomania is a danger, therefore, which must be carefully held in view. *British Medical Journal.*

## LARGE ŒDEMATOUS MYOMA—HYSTERECTOMY—RECOVERY.

By NEIL MACPHATTER, M.D.,

DENVER, COL.

The recording of the ordinary cases now met in abdominal surgery has long since ceased to be of more than passing interest to the gynecologist. What, however, appears to me to be an interesting case, on account of the difficulties of making a positive diagnosis and at the same time illustrating the fact, not too urgently insisted upon, that it is absolutely impossible to tell beforehand what complications may be encountered in the removal of abdominal tumors. The point advocated by those surgeons, that tumors having adhesions can be distinguished from uncomplicated ones has not received sufficient proof. Upon the other hand I maintain, from what I have seen in this branch of the profession, that absolute accuracy in the diagnosis of complications cannot be attained before opening the abdomen. Without compunction I can even go further and say that accuracy in the diagnosis of tumors is far from being perfect, let alone the complications which may or may not be present. Only the novice or the ignorant assert otherwise. A case illustrating in a remarkable manner the points I have advocated came under my observation some time ago. Believing it to be of sufficient interest to the profession, I bring a *résumé* of it before your readers.

On June 15th last, while in the East, I received from Dr. William Gunn, of Clinton, Canada, a letter stating that a patient of his had a tumor that had been growing for several years, and as she was gradually losing strength, wished to know if I would go over and operate. I replied in the affirmative, and a few days subsequently received a telegram to come on. On account of the delay of trains I arrived too late to operate on the day I had appointed. I received the following history of her case: Mrs. C——, aged forty-two years, married twenty-one years, the mother of five children, having her last ten years ago, had never been well since the birth of her last child. She experienced a dragging sensation and periodical attacks of pain in the lower part of the abdomen. These symptoms continued, and five years ago she noticed a lump in the region of the womb. There were added now feelings of pressure upon the rectum and bladder. The attacks of pain became much more severe, and were occasionally attended by febrile symptoms. I attach particular importance to this latter symptom, as accounting for some of the complications which were encountered at the operation. The tumor had gradually increased in size until it now filled the whole abdominal cavity. She was thin and worn-out looking, and had a drawn, pinched expression of suffering on her face. Dr. Gunn had remained in doubt as to what kind of a tumor it was, and upon examination I soon found he had good reason for his uncertainty. The tumor filled the whole abdominal cavity and was uniformly round and smooth, presenting every feature of an ovarian cystoma. The fluctuation was quite distinct in every direction. From the fact that the uterus appeared to be intimately associated and apparently implicated in the enlargement, and the knowledge that the sound could be passed full length into the uterus, I concluded and was inclined to believe the tumor to be a myoma of the soft œdematous variety, and that hysterectomy would be necessary. The almost constant feature of hemorrhage that accompanies myoma was absent, and the doctor had passed a hypodermic needle and drawn fluid from the tumor, so there were many reasons for hesitancy in pronouncing upon an absolute diagnosis. I had, however, seen a number of such cases so that I inclined to the belief of œdematous myoma, although I was in no way positive.

I have now come across a sufficient number of the

soft œdematous variety of myoma to make me believe they are much more common than is generally acknowledged. Space will not allow me here to go into the full details of this interesting subject, further than to say that there are two varieties of myoma, the hard multinodular kind, and the rapidly growing soft œdematous variety. They are both quite distinct in their history, symptoms, appearance, pathology, and treatment. The soft œdematous kind simulates ovarian cystoma and pregnancy so closely that it is often difficult and impossible to distinguish between them. Indeed, I have upon two occasions seen one of our most brilliant English surgeons in a quandary, even after the abdomen was open and the tumor exposed to view. The uterine tissues frequently envelop and surround the tumor exactly as in pregnancy. This variety appears at any period of life from puberty to old age, and does not arrest its growth at the menopause as does the other variety. This proves that the soft œdematous myoma is a condition that is not in any way affected or influenced by menstruation, and therefore we cannot expect it to gradually diminish and disappear after the climacteric, nor is the removal of the appendages of any avail. Hysterectomy is the only remedy for these cases. The hard multinodular variety, on the other hand, should never be mistaken for ovarian cystoma or pregnancy, and is a disease entirely of menstrual life, coming on usually between the ages of twenty and forty years. It has no fluctuation, and does not grow so rapidly nor to such a size as the other. It is influenced wholly by menstruation, and begins to diminish, and gradually disappears after the advent of the menopause. When the hemorrhages that accompany this variety are so frequent and profuse as to threaten life before the climacteric comes on the removal of the appendages is clearly indicated, although it is sometimes very difficult to find them on account of the size of the tumor.

The next morning at 9 A.M. I proceeded to operate. There were present Dr. Gunn, who assisted, Drs. Worthington and Williams, of Clinton, and Dr. Elliott, of Brucefield, who administered the anæsthetic. On the incision being made through the parietes I discovered that it was an œdematous myoma, and I proceeded to do hysterectomy. The incision was extended upward when I discovered the tumor was intimately adherent everywhere, I passed my hand and forearm in and broke up as many as I could. With a corkscrew inserted into the tumor I drew it out as far as adhesions would allow. These were broken down and making another effort to draw the tumor out, I found the transverse colon, small intestines, and omentum tightly adherent at the top. After a good deal of tearing I succeeded in getting them liberated, although there was considerable bleeding. Parts of the omentum that appeared gangrenous I tied and cut away altogether. When I had the adhesions all liberated and the tumor drawn out of the incision the whole of the peritoneum on the back part of the abdominal cavity came away with it. The right ureter was attached about six inches along the tumor and was drawn completely up out of the cavity. After careful dissection it was set free but found to be about twice its normal length from the zig-zag way it was incorporated in the tumor. When dropped back it lay like a coil of small rubber tubing. I examined the corresponding kidney for enlargement but as far as I could judge from feeling there was no pathological condition. I have seen several hundred abdominal sections, but never before met with this complication. The muscles along the back and pelvis, the left ureter and vessels were quite bare. The arteries could be seen pulsating quite distinctly. There was a great deal of general oozing everywhere. Many of the points were tied, others were controlled by forceps and hot sponges. To make it complete the bladder was adherent in front. I was obliged to cut the peritoneal covering above the fundus in a horizontal manner and then peel the bladder down. The bleeding from this was scarcely worth mentioning. A temporary clamp was passed around the tumor near its base, and tightened. This controlled all hemorrhage from the broad ligaments and rendered the subsequent steps of the operation more easy. The tumor, including uterus, ovaries, and tubes, was now cut away close to the temporary clamp. The permanent serre-nœud was now substituted for the temporary one and screwed as tightly as advisable. The staple was passed through close to the cervix, and all redundant tissue above this trimmed off. The general bleeding was still very considerable and took some time to properly check, as many clots as possible were swabbed out with sponges and the whole abdominal cavity most completely washed out. The abdominal incision was next stitched up and brought to fit as closely as possible around the pedicle. There were so many ragged edges from torn adhesions that I deemed it advisable to put in a drainage-tube. It is fortunate I did so, as there was considerable discharge sucked up by the syringe for nearly three days. The stump was thoroughly cleaned and ordinary dressing applied over a saturated solution of perchloride of iron and glycerine. The patient was placed back in bed and rallied remarkably well from the shock. Hot bottles were packed about her and enemas of beef-tea and brandy given at intervals. This had a beneficial effect, the pulse gradually becoming slower and of better volume. During the first night she was very restless and complained of pain and a sinking, smothering sensation in her chest, this was probably owing to the effects of the anæsthetic and the balance of circulation being upset. The following morning she expressed herself as feeling more comfortable but very nauseous. This tendency to vomit continued for some time and was a very troublesome feature in the after-treatment. I am indebted to Dr. Gunn for a full report of the after-treatment and I desire here to write of the excellent arrangements he had made for the operation and my appreciation of the skilful manner in which he continued the case afterward.

Notwithstanding the numerous adhesions that were broken up, and the large area of raw surface that was left, the temperature remained normal for eight days, when, owing, no doubt, to stitch abscesses, and the sup puration accompanying the sloughing process about the pedicle, it went up slightly and ranged from normal to 101½° F. This good result I attribute largely to the manner adopted in washing out the abdominal cavity, and drainage. Thanks to the genius of Lawson Tait, the abdomen can now be cleaned of all clots and *débris*.

The urine was drawn off for four days, and the bowels moved by an enema upon the fifth. The stitches were removed on the sixth and ninth days. On the fourth day Dr. Gunn cut the wire of the serre-nœud and withdrew the handle, leaving the wire to come away with the pedicle, which sloughed off on the twelfth day. On the thirteenth day a well-defined lump could be felt on the right side of the pedicle. Suspecting pus or blood, Dr. Gunn made an opening into it, and evacuated a considerable quantity of both blood and matter. The history from this out was not marked by anything of importance. The wound gradually healed up, and the patient recovered completely. I have just received a letter from Dr. Gunn, wherein he says: "The patient feels perfectly well in every respect. It was an interesting case, showing the difficulties of making a diagnosis, the size of the tumor, and especially the fact that she recovered."

What would have been a disastrous accident was narrowly escaped during the operation. There were so many adhesions of all sizes attached to the growth as I drew it out, that I at first did not recognize the ureter as such, and was almost in the act of breaking it down with other stringy bands of adhesions, when I noticed the peculiarly rounded and uniform size to be the organ. It was marvellous how it escaped being torn when drawn out with the tumor, as it was on extreme tension. After liberating it, I felt not a little uneasiness lest its lumen be occluded, and disease of the corresponding kidney would result, necessitating, at a subsequent date, an operation for its

removal. From the fact that I could detect no enlargement of the kidney at the time, and that no symptoms relative to it have since appeared, I have reason to believe the ureter to be fulfilling its functions properly.

Here I would like to say that I cannot imagine intestines, be they ever so intimately attached to a tumor, providing, of course, they are not gangrenous from pressure or want of blood-supply from the mesentery, but what they can be, with a little patience and care, liberated. I say this to particularly mark my disapproval of a method that was recently pursued in a similar case in one of the London hospitals. In that instance the operator found intestine that was not gangrenous adherent to the tumor, and instead of liberating it in the usual manner, and because, as he said, of the numerous experiments he had recently been making in intestinal surgery on dogs, he cut the intestine through in two places and sewed the ends together, only to find, as might be expected, a few days subsequently, that the bowel ruptured at the seat of union, or rather non-union, and set up fatal peritonitis. Here is the statement as reported by the operator himself: "I then found that a portion of the intestine was so intimately incorporated with the growth that it was found impossible to detach it without tearing the bowel or detaching some of the growth. Under these circumstances, guided by experience of numerous experiments I had lately made in intestinal surgery, I determined to cut away all the intestine implicated, and join the two ends together." At the post-mortem it was discovered that the rubber ring used did not pass down but remained as an obstruction; "then the rubber ring had acted more or less as a valve, and prevented the fæces from passing. This caused distention of the gut above the seat of operation; ulceration along one of the ligatures, perforation, peritonitis, and death." Such work as this will surely not enhance the welfare of the profession, but is absolutely damaging and discreditable. No operator should forget his duties in such an emergency when the results are weighed against the slim chances hinging upon the knowledge gained from experimenting upon the intestines of dogs. The results of experiments, especially upon the intestines of dogs, are fraught with danger when applied to abdominal surgery.

Steele Block, Sixteenth Street.

## Progress of Medical Science.

Death from Sublimate Irrigation after Abortion.—Seven years since, Tarnier introduced the practice of washing out the vagina with weak corrosive sublimate injections. The results proved satisfactory, and the injections came into vogue in German and English, as well as in French, lying-in hospitals, extending freely into private practice. Like every thorough method of counteracting deadly agencies in the human organism, sublimate irrigation is not free from danger, and although it greatly reduces the death-rate and proportion of puerperal fever cases in long series of labors, some cases of mercurial poisoning will occur in those series, notwithstanding the most careful administration of the remedy. In England, Drs. Dakin and Boxall have published very minute observations on mercurialism under the above-noted conditions. They appeared in the *Transactions of the Obstetrical Society* for 1886 and 1888. Dr. Legrand read before the Anatomical Society of Paris, in April, a case of twin abortion, retained placenta, and death from acute mercurialism. Between the birth of the first and second child, ten quarts of a 1 to 2,000 solution of sublimate were employed to wash out the uterine cavity, twice, at an interval of three hours only. Immediately after each injection of sublimate a two per cent. solution of boracic acid was thrown up into the uterine cavity; but sublimate had been several times employed for vaginal injection. After the extraction of the second child the boracic solution was injected into the uterine cavity. The intrauterine injections were discontinued, and boracic and carbolic solutions were used for the vagina. A day later gingivitis, salivation, colic, and dysentery set in, and carried off the patient in five days. The kidneys were large, pale, and very œdematous; they contained mercurial salts in solution. The palate was ulcerated; the œsophagus, stomach, and small intestine healthy. The mucous membrane of the entire large intestine was covered with eschars and ulcers, most marked on the summits of rugæ. The ulcers began in the cæcum, were least abundant in the transverse colon, and most marked toward the anus. The above conditions have been noted in many other cases of death after sublimate irrigations in childbed. The kidneys were diseased. Keller, of Berne, has already pointed out the danger of mercurial irrigation when these organs are not healthy. The English authorities just quoted both dwell on this danger. Dr. Legrand relates that the ulcerated intestinal mucosa swarmed with bacteria. This fact, he adds, must make us despair of insuring intestinal antisepsis by means of corrosive sublimate.—*The British Medical Journal.*

The Operative Treatment of Tubercular Peritonitis.—Dr. F. Spaeth has reported four cases of tubercular peritonitis, treated by laparotomy, in Dr. Prochownick's clinic in Hamburg. The patients were all females between the ages of thirty-two and forty-three (*The Annals of Surgery*). The symptoms differed greatly in the four cases, but in all the inguinal glands on both sides were considerably enlarged. In every case tubercle bacilli were found. The author thinks this very important, for many cases of chronic disease of the peritoneum, which at first sight appear to be tubercular, are found on microscopic examination to be nothing more than a peritonitis with a nodular formation, a simple lymphoma of the peritoneum. To these errors of diagnosis may be attributed in some cases the unsuccessful results of laparotomy. So far little attention has been paid to the demonstration of tubercle bacilli in the excised pieces. Thus in forty-one of Kümmel's cases the results of the microscopical examination are only mentioned in eleven cases, and in only five of these were bacilli reported present. Of the writer's cases, one died of collapse five days after operation, to which condition a marked atrophy of the kidney contributed in a large degree. The second case died of acute phthisis three months after operation. The third case died of intestinal tuberculosis, and the fourth is now dying of the same disease. The unfavorable results cannot be attributed to the operation. The author terminates his paper with the following conclusions: 1. In primary tuberculosis of the peritoneum without implication of other organs, laparotomy may act as a curative agent and is to be recommended. 2. In tuberculosis of the peritoneum, where the female genitals are involved in the process, the operative treatment has not given any satisfactory results. 3. In tuberculosis of the peritoneum due to a tubercular enteritis, the operative treatment is only palliative. 4. In genital tuberculosis, unaccompanied by peritoneal tuberculosis, early radical operation is to be urged. The indications for operation are not readily determined, owing to the almost impossibility of making a bacteriological diagnosis before laparotomy. 5. Primary tubercular peritonitis is a much rarer form of disease than has heretofore been thought. Hence care should be exercised in making a diagnosis, and a bacteriological examination of every case should be made.

---

Actinomycosis Hominis.—Dr. L. Ammentorp reports in the *Nordiskt Medicinskt Arkiv*, No. XXIV., four cases of actinomycosis in men—two of the upper jaw, one of the lower jaw, and one of the lung. In this last case the patient had worn a tracheal cannula for several years. The author regarded the case as one due to infection through the inspired air, a mode of transmission of the disease not hitherto recognized.

## PLASTIC BRONCHITIS.

THE literature of this rare disease was reviewed in 1869 by Lebert in the *Deutsches Archiv. für Klin. Medicin.* In the twenty years which have since elapsed somewhat more than fifty cases have been reported. In the *Practitioner*, August, 1889, Dr. West of London gives the results of a careful collation of these fifty odd cases, including one which occurred in his own practice.

In this latter case the patient, a woman, forty years of age, had enjoyed perfect health until she was suddenly attacked, two years before she came under observation, by what seemed to be asthma, the paroxysms becoming more and more frequent until they occurred every twenty-four hours. They were asthmatic in type but without cyanosis, the patient being awakened by the onset of dyspnœa every night at about two o'clock. After the paroxysm had lasted two or three hours free expectoration occurred, and relief was obtained by the patient. The diagnosis of asthma was at length questioned, because of the sudden onset of the paroxysms only two years before and because of the remarkable periodicity of the attacks, and plastic bronchitis was suspected. Upon examination of the sputum, this suspicion was confirmed by the discovery of small but numerous bronchial casts, grayish-white, mucoid in appearance, much ramified, the largest being as thick as a goose-quill and two and one-half inches long. There had been no hæmoptysis, there were no abnormal signs upon examination of the chest, the general health was fair, there was no fever or night-sweating, but some depression from loss of sleep. Various drugs were used without effect, and after six weeks' treatment the patient was discharged as ill as ever.

In the review given by Dr. West of the whole subject many important facts concerning this strange disease are developed. It occurs at all periods of life, but is more frequent in middle-aged males. It is characterized by the occurrence of paroxysms of dyspnœa and cough, which cease at once upon expectoration of the casts. The paroxysms are usually preceded and followed by a sort of catarrh. Hæmoptysis may be absent, or it may be very serious. It generally ceases at once with the ejection of the casts. There is usually but little pain, except that which is caused by coughing. In acute cases the temperature may rise to 104° F., in chronic cases it is not often above normal. Sometimes the onset of an attack is marked by one or more rigors, which may be so severe as to suggest pneumonia. As a rule each attack consists of a number of short paroxysms. It may subside after a few days, never to recur, or it may last continuously for as long as ten years, or it may be repeated at regular intervals (as at each menstrual period). Cases have been reported in which more than ten years have intervened between the attacks. The disease is seldom fatal, but death may occur from other antecedent or intercurrent diseases.

Plastic bronchitis is associated in a few cases with phthisis. Sometimes it appears a few weeks after recovery from pneumonia. Pleurisy may be coincident with it. Syphilis is sometimes present. Occasionally it follows scarlatina or typhoid fever. In four cases it was accompanied by severe diseases of the skin—pemphigus, impetigo, and herpes zoster. Pregnancy may cause cessation of the attacks.

The diagnosis of plastic bronchitis is possible only upon the expectoration of the characteristic casts; but besides this it is necessary to exclude pneumonia on the one hand, and croup or diphtheria on the other. Those cases only are to be classed as plastic bronchitis where the paroxysms with this peculiar expectoration occur in the absence of pneumonia, or where they follow pneumonia after several weeks' interval, or where they exist for some time before pneumonia (which in this case is probably caused by them) sets in. Cases must also be excluded in which the casts are formed in the course of croup or diphtheria. The physical signs in uncomplicated plastic bronchitis are very indefinite. There are usually evidences of chronic catarrh; but the rhonchus and sibilus may be limited to the region about the cast, and sometimes an evident obstruction to the tubes in some part of the lung may disappear when the cast is expectorated. Dulness at the base behind may be due to collapse or pneumonia.

The expectoration is muco-purulent and varies in quantity. The casts are formed of fibrin deposited in concentric laminæ. Amid the fibrin are enclosed small cells, a few epithelial cells, and sometimes ciliated epithelium. The casts are branched; the smallest branches solid, the larger perhaps with a central lumen. Sometimes only one cast is expectorated in two or three days, at other times, or by other patients, very many may be coughed up each day. Often the casts are very much more abundant at night. There is no specific treatment for the disease. Inhalations, especially of lime-water, are much praised, but it is doubtful whether they really do good. Iodide of potassium is the only internal remedy generally recommended by those who have treated these cases. Sometimes complete cure has followed its use, and often partial relief has been reported.

## GALACTOCELE TESTIS.

COLLECTIONS of milky fluid in cysts, or in the natural cavities of the body, are now and then reported in our medical journals. In some cases the fluid is found, upon microscopic examination, to contain the *Filaria sanguinis hominis*, a parasite which causes also chyluria. Of this nature, probably, are the cases of hydrocele observed in tropical regions, in which the fluid drawn off by the surgeon is white like milk. The diagnosis in such cases is readily made when the fluid is placed under the microscope, the microscopic field being crowded with the characteristic parasites.

In other cases collections of whitish fluid in the scrotum are found, upon examination, to contain semen. This semen is sometimes normal, being full of vigorous, quickly-moving spermatozoa; sometimes it contains tailless spermatozoa, the true nature of which may be determined by staining with hæmatoxylon, etc.

The cysts which contain this seminal fluid are developed in connection with the epididymis, and may be of great capacity, containing as much as twelve ounces of the milky fluid. This seminal fluid is not found in the cavity of the tunica vaginalis, although it is possible that the cysts formed about the epididymis may burst into that cavity.

In the *New Orleans Medical and Surgical Journal*, September, 1889, Drs. Cocram and Miles report a case of milky fluid in the cavity of the tunica vaginalis which seems to belong to a hitherto undescribed class.

The patient applied at the hospital, suffering apparently from some serious nervous trouble. He was hypersensitive, and very much excited, losing control of speech when questioned, and unable to fix his attention upon any subject. He stated that, three months before, he had observed a swelling of the scrotum, and that this swelling had steadily increased. Examination showed a tense scrotal tumor, containing at least a pint of fluid. Desiring to confirm his diagnosis, the surgeon introduced the needle of a hypodermic syringe. Much to his astonishment, an opaque liquid of about the color and consistency of milk was withdrawn. Upon microscopic examination by a pathologist the liquid was found to contain a great multitude of light, almost transparent, granules, which were all in very active motion. These could not be fat-granules, because they did not refract light strongly and because they had the Brownian movement. Three cover-slips smeared with the fluid and dried (according to the method used in searching for bacillus tuberculosis) were stained, one with magenta (Ziel's solution), one with methyl blue (Loefler's solution), and one with hæmatoxylon. Instead of becoming fixed and stained, and appearing as distinct points, as bacteria would have done, the granules were now replaced by large films of coagulated or hardened albuminous matter, like the streaks of mucus seen in staining sputum. Furthermore, the fluid was odorless, whereas if it had been thronged with bacteria it would have been fetid. The pathologist was of the opinion that the granules were particles of albuminous matter (non-reproductive), having the Brownian movement.

A second examination of the tumor was made five hours after the first, when it was found that it had diminished during this time, by two-thirds its original capacity. It was now loose and flabby, conveying to the touch a gelatinous sensation of redundant tissue. The fluid was evidently contained in the cavity of the tunica vaginalis. Next morning the scrotum was nearly normal in size. The patient was dismissed cured twenty-four hours after admission, no treatment except the single hypodermic puncture before mentioned having been used. Five days later the fluid was still diminishing. There was the same gelatinous feeling, but somewhat firmer.

The tumor had developed like a hydrocele. Throughout its course there was no constitutional disturbance. It was not due to chylous ascites, for there was no communication between the cavity of the tunica vaginalis and that of the peritoneum. As far as the writers knew, it was a unique case.

---

## THE "BELLY-DISORDER" OF CHILDREN.

THE announcement of a new disease, and especially a new disease of children, will, in this day, be received with some incredulity. Dr. R. A. Gibbons, of London, states (*Edinburgh Medical Journal*, October, 1889), that "the cœliac affection of children" is a disorder which has not been described in text-books, but is one of great importance, for the disease, though not very common, ought always to be recognized. The name "cœliac affection" is bad enough, for it means only an affection of κοιλία, the belly. As the pathology of the disorder, however, is unknown, a name indicating nothing specific may serve the purpose for the present.

The cœliac affection (*anglice*, belly-trouble) of Dr. Gibbons, is the name for a disease which in hospitals is sometimes spoken of as consumption of the bowels. It occurs in children between the ages of one and five years, and its striking peculiarity is that, despite its severe and often fatal course, no lesions are found post-mortem.

The onset of the disease is usually gradual. The child becomes pale and anæmic. Perhaps the first thing especially noticed is the changed color and fetid odor of the fæces.

This malodor, says Dr. Gibbons, is sometimes overpowering, and those who have not encountered it can hardly realize it. The motions themselves are very large, soft, whitish in color, and frothy. They resemble very much ordinary oatmeal porridge. The actions may be two or three in a day, but usually there is only one large one, and that may take place at a time to which the child is accustomed. Now and then there are attacks of so-called diarrhœa, that is to say, the child may have frequent evacuations of the bowels; that they may be very loose, and that they may be occasionally watery if the attack is severe; but these attacks of diarrhœa are not an essential part of the disease, except in the cases of some children who have these constant attacks of diarrhœa throughout the whole of the illness. The appetite is poor, usually capricious, sometimes large. The tongue is frequently coated with a whitish fur, at other times perfectly clean. In some cases there are attacks of crampy abdominal pain, possibly due to ordinary colic.

The most remarkable symptom, according to our writer, is that of loss of muscular power, with apparently no great loss of flesh.

The progress of the disease is slow, and its termination often fatal.

The diagnosis, according to Dr. Gibbons, presents no trouble. Great stress is laid upon the examination of the evacuations, their fetor, and the absence, ordinarily, of sufficient diarrhœa to cause the severe symptoms.

It is insisted that examination of the bowel and other organs, after death, reveals absolutely no lesion.

The treatment consists in very careful nursing and attention to diet; cream, whey, pounded rare meat, mashed floury potato, are among the articles recommended by Dr. Gibbons.

## News of the Week.

THE AMERICAN ACADEMY OF MEDICINE.—The American Academy of Medicine will hold its Thirteenth Annual Session at Leland's Hotel, Chicago, Ill., on Wednesday and Thursday, November 13 and 14, 1889.—RICHARD J. DUNGLISON, M.D., *Secretary.*

THE ANNUAL MEETING of the New York Physicians' Mutual Aid Association will be held at the Academy of Medicine on Thursday, November 14th, at 4 P.M.

THE LATE DR. ISAAC E. TAYLOR.—The following resolutions were offered by the Board of Obstetric Surgeons of the Maternity Hospital on the death of Dr. Isaac E. Taylor. *Resolved*, That in the death of their late President, Dr. Isaac E. Taylor, the members of this Board have met with an irreparable loss—the loss not only of a faithful and efficient colleague, but of a warm personal friend. *Resolved*, That in his beautiful and serene old age they recognized the noblest type of the good physician, who retired from the active practice of his profession in the fulness of his fame and with the universal love and respect of his associates. *Resolved*, That they extend to the family of the deceased their heart-felt sympathy, and that they will unite with them in cherishing his memory. *Resolved*, That copies of these resolutions be sent to the family and to the medical journals.—HENRY C. COE, M.D., *Secretary.*

A NEW MEDICAL COLLEGE BUILDING.—Work has been commenced on the new building for the Medical College of the New York Infirmary for Women and Children, at the corner of Livingston Place and Fifteenth Street.

NEW YORK CITY BOARD OF HEALTH.—The Board of Estimate and Apportionment has cut down the appropriation for the expenses of the Health Department for the year 1890 from $417,096, the sum asked for, to $391,500. Among the items in which the allowance is reduced are hospital supplies, $4,800, and disinfectants, $3,700. For the present year the total allowance for the department was $413,600.

THE HUDSON RIVER STATE HOSPITAL.—The New York State Hospital at Poughkeepsie has received an appropriation of $40,000 with which to build additional accommodations for the resident staff and one ward for the isolation of infectious or suspicious cases.

THE MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND is a venerable and highly respected organization with a flavor of antiquity in its name and a suggestion of decadence in its membership-list. The State of Maryland supports over two thousand physicians, but the State Society numbers only two hundred and eight of these. An appeal has been made for larger membership.

EXPERT TESTIMONY AT THE CRONIN TRIAL.—Expert testimony, so called, has received a well-deserved rebuke at the hands of the lay press, in connection with the Cronin trial. The medical evidence produced by the State to prove the identity, injuries, and cause of death in the case of Dr. Cronin was inexcusably stupid. The results of the autopsy are absolutely of no value because of the ignorance or carelessness of the persons conducting the post-mortem. What should have been an exceedingly thorough and scientific examination of the body found in the Lake View catch-basin appears from the evidence produced in court to have been a sort of hit or miss affair, in which various individuals, who, unfortunately for the cause of science, have medical diplomas, took a more or less prominent part. It is just such "free for all" medical examinations with the resulting "expert" testimony that brings well-merited disgrace upon the medical profession before our courts of justice. The necessity of some legal ruling as to who shall be considered an expert is absolutely necessary. The criminality of allowing ignorant and stupid politicians to fill medical offices as a reward for past political defeats is painfully manifest in the present notorious case on trial.—*Medical Standard.*

THE PRESIDENT OF THE NEXT INTERNATIONAL MEDICAL CONGRESS is Rudolph Virchow; the Secretary is Dr. Lazar.

THE CARTWRIGHT LECTURES this year will be delivered by Dr. J. S. Billings, of Washington, D. C.; the subject will be "Vital and Medical Statistics."

THE LATE M. RICORD.—Among the last acts of Ricord's life, says the *British Medical Journal*, was the ascent of the Eiffel Tower, and his death was hastened by his coming from Versailles to Paris to vote for the Republic in very inclement weather. Having to wait on the platform, he contracted a severe cold, and was attacked with double pneumonia. Only a few days before his death, one of his friends, on seeing him, said to him: "*Mais, mon maître, vous avez bonne mine.*" His characteristic answer was: "*Mon ami, je ne vous conseille pas de prendre des actions dans cette mine-là.*" A charming *calembour*, which showed that to the last he retained all the brightness of his inimitable wit and gayety of spirit. His kindness to young men, his generosity to the poor, his hearty welcome and unbounded liberality to foreigners, and his cordial hospitality to all English visitors did much during all his life to render him and his profession popular with all visitors.

BRITISH HYPNOTIC SOCIETY.—It is stated that a number of eminent London physicians have organized a "Hypnotic Society," for the purpose of studying hypnotic phenomena, and securing a law prohibiting public séances of hypnotism, mesmerism, etc.

A DISCUSSION ON HYSTERIA recently took place at the Gratiot County Medical Society, in which a highly interesting profundity and yet diversity of medical opinion was shown. After the reading of a paper on hysteria by Dr. Brainerd, and various comments thereupon, a series of questions was submitted with the following brilliant results—results calculated to send the Gratiot County Society thundering down the ages as the great source of true illumination upon this obscure subject: 1. "Are most of your hysterical patients fat?" Kennedy, "Yes." Carpenter, "No." Scott, "No." Brainerd, "Yes." 2. "Are not the trance cases reported in the papers hysterical?" Kennedy, "Yes." 3. "Is it best to inform the patient that she has hysterics?" Scott, "Yes." Kennedy, "No." Carpenter, "No." Barber, "Yes." Hatt, "Yes." Kennedy: "You'll only offend the patient and freeze yourself out of the case." And yet some people deny the utility of medical societies.

REGULATIONS AND PROGRAMME OF THE TENTH INTERNATIONAL CONGRESS.—The general rules and regulations of this Congress have been sent out by the General Secretary, Dr. Lassar, of Berlin. These relate to the organization of the Congress, and resemble the regulations that have always been issued regarding the meetings. I. The Congress is to open on Monday, August 4, 1890, at Berlin, and to close on Sunday, August 10th. II. The Congress is to consist of regular, licensed (*approbirten*) physicians, who have enrolled themselves as members and obtained members' cards. Other learned men interested in the work of the Congress can become associate members. The cost of membership will be twenty marks (about $4). III. The objects of the Congress are exclusively scientific. IV. The work of the Congress will be done in eighteen sections. VII. The general sessions will be devoted to (*a*) the measures regarding the general regulation of the Congress, and (*b*) addresses and communications of general interest. VIII. Notices of papers to be read and abstracts of them must be sent to the Organization Committee before July, 1890. IX. Written copies of the articles to be read must be sent to the Secretary of the Section before the conclusion of the session. XI. The official languages will be German, French, and English. XII. Communications must be limited to twenty minutes, and discussions to ten minutes. XIII. The sessions will be regulated by generally received parliamentary rules. XIV. Students of medicine and others interested in the work of the sessions can be admitted by securing invitations. XV. Communications or questions regarding the work of the special sections should be addressed to the President of the Section. Other communications should be addressed to the General Secretary, Dr. Lassar, Berlin, N. W., Karlstrasse 19.

MEDICAL PARIS has been interested during the week by the marriage of Dr. Bertillon, the distinguished head of the Department of Medical Statistics for the Department of the Seine, with Mademoiselle Schultz, a lady who passed recently a brilliant examination for the diploma of Doctor of the Paris Faculty of Medicine.

THE TRADE OF MEDICINE IN GERMANY.—A correspondent of *The Occidental Medical Times* writes somewhat gloomily regarding the condition of medical affairs in Germany. He says: "Another serious grievance under which we labor is the definition of the legal code, by which the medical profession is classed, *pro pudorem hominum*, as a trade (*ein Gewerbe*). In Germany, a duly qualified practitioner has, beyond his superior knowledge, positively no advantage whatever from his diploma in the contest with quacks and charlatans. Of course, if a patient treated by a quack takes an unfavorable turn, the case is sometimes inquired into by the authorities, and occasionally the pseudo-practitioner is duly punished. But, on the other hand, if a qualified doctor commits any serious mistake, he undergoes just as severe penalties here as anywhere else. It is only a little while ago since a physician of Lübeck, Dr. Binder, was sentenced to several weeks' imprisonment for an *error artis*, and would undoubtedly have been put in jail, but for a petition to the Senate, signed by some thousands of his friends and patients, craving his pardon. As, furthermore, the *irregular* practitioner has the advantage of being able to advertise and to use other means of attracting patients which are naturally denied to the profession, it very frequently happens that a deluded public lay both gold and glory at the feet of the astute charlatan. And as if this were not enough, there are even clubs which acknowledge a certificate from such autodidacts as equivalent to that of a qualified man. In the new code of civil laws, with which the nation is to be shortly benefited, this state of affairs appears destined to be rendered permanent by the sanction of the highest authorities, for in the paragraphs dealing with the question of remuneration for medical services, the profession is simply classed with artisans, midwives, and all other persons who do work or perform medical services for which they receive payment, *i.e.*, quacks. This degrading paragraph, I am happy to say, has already raised so much righteous indignation that we may hope to see it removed or altered before the final passage of the law. Prince Bismarck, however, in spite of his having experienced so much benefit from Professor Schweninger's application of Oertel's method to his case, was ungrateful enough not to accede to the request of the Physicians' Association, asking for an official inquiry into the legislation on medical affairs, so the profession may look out and shift for itself. The organization of a central body of representatives for the material interests of the faculty, with branch sections throughout the empire, as has recently been instituted under the auspices of the Minister for Science, von Gossler, is therefore all the more welcome and valuable. Although still too young to have effected any material change, it is to be hoped that this arrangement will, in future, be productive of much good."

THE ETIOLOGY OF PNEUMONIA.—Apparently some attention is due to Dr. Henry B. Baker's ingenious theory of the etiology of pneumonia. This theory has been set forth in *Science*, but it has been fortified by statistics elsewhere. Dr. Baker asserts, as a demonstrated fact, that in any given place, wherever studied, pneumonia is quantitatively proportional to the coldness and dryness of the atmosphere; and as this is true for every month of the year, it follows that, if there is any pneumonia which is infectious, it is absolutely dependent upon those meteorological conditions for its action upon the human organism. He further asserts that the expired air in cold, dry weather contains a relative excess of water; hence the lung-tissue is dehydrated, and chloride of sodium accumulates in it. This condition seems to favor the development of the pneumonic infection.

CHRYSAROBIN IN HÆMORRHOIDS.—Dr. Kossobudskii speaks of this drug in high terms, but he differs from Unna in the quantity. Dr. Kossobudskii uses a two and a half per cent. instead of a five per cent. as Unna prescribes. After washing the swelling with a two per cent. lotion of carbolic, or a one per cent. of creolin, he recommends the following ointment to be applied twice or three times a day:

℞. Chrysarobini ..... 0.8
Iodoformi ..... 0.3
Ext. belladonna ..... 0.6
Vaselin ..... 15.0
M.

Or a suppository may be made with cocoa butter. If bleeding be present tannin may be combined. Dr. Kossobudskii affirms that pain, smarting, and bleeding will disappear in three or four days.—*Medical Press.*

# Society Reports.

## NEW YORK ACADEMY OF MEDICINE.

### SECTION ON THEORY AND PRACTICE OF MEDICINE.

*Stated Meeting, October* 15, 1889.

R. C. M. PAGE, M.D., CHAIRMAN.

DR. A. JACOBI read a paper on

### CHRONIC PERITONITIS, WITH SPECIAL REFERENCE TO THE DIFFERENTIAL DIAGNOSIS OF SOME OF ITS VARIETIES.

Primary peritonitis of any kind, he said, was very rare. When it occurred it was mostly the result of wounds, including paracentesis for ascites. Other cases resulted from exposure and cold. Most of the cases, however, were of a secondary nature, with very numerous causes. Thus it might arise under the influence of general diseases, such as rheumatism, alcoholism, scarlatina, measles, malaria, scurvy, tuberculosis, and carcinosis. The inflammation of the neighboring thoracic cavity might be transmitted through the patent stomata of the lymph-ducts on the upper and lower surface of the diaphragm, and disorders of circulation depending on pulmonary and cardiac diseases would result in congestion of the peritoneum, both visceral and parietal, with its possible consequences, inflammation or effusion.

The presence of new-formations in the abdominal cavity acted like that of a foreign body; and in this connection ovarian tumors, sarcoma of the kidney, and swelled pelvic glands associated with irritated and tumefied inguinal and mesenteric glands were referred to. A young woman that he saw dying of acute peritonitis had been affected with purpura for some weeks, and at the autopsy the peritonitis was found to have resulted from hemorrhages from some ruptured vessels of the diaphragm. Floating kidney, by its changing position and irritating contact with the peritoneum, was quite liable to light up a chronic inflammatory process. Other causes of peritonitis mentioned were, affections of the vertebral column and adjoining parts, such as spondylitis, and abscesses of the psoas and iliac muscles and of the acetabulum, and catarrhal and inflammatory diseases of the female sexual organs. The irritation or inflammation of any of the organs contained in the abdominal cavity was liable to produce peritonitis, and intussusception in infants was especially referred to.

Perhaps the most frequent cause of peritonitis was a preceding peritonitis. Indeed, in most cases examined after death the positive proofs were found of one or more attacks previous to the fatal one. Dr. Jacobi said he did not remember a case of perityphlitis that did not exhibit the adhesions, discolorations, and contractions due to former peritonitis; and he thought it probable that there were but few, if any, cases of foreign bodies entering the vermiform process unless the latter had previously lost its elasticity and contractility by an inflammatory change.

Alterations of the mucous membrane of the intestine constituted the initial stages of local peritonitis in many instances, and of general peritonitis in some. It was not only the *intima* and the submucous tissue which suffered, but the muscular layer was also implicated in the morbid process. The vascular connection between the three principal layers of the walls of the intestine was such as to facilitate the transmission of an inflammatory process from one to another, with the result of giving rise to œdematous infiltration, paralysis, and constipation. Thus it was also that a mere diarrhœa was able to develop, in a shorter or longer time, a local peritonitis. No morbid process could remain isolated in a locality supplied with an active blood and lymph circulation, and hence an intestinal catarrh grew to be an enteritis, the enteritis a peritonitis.

This condition of things was still more frequently observed in cases of intestinal ulceration, both acute and chronic. Even without perforation an ulceration would lead to peritonitis which is mostly local, but liable to change into an acute attack under favorable circumstances. Where there was an open ulcer, or even one that had cicatrized months or years before, in the stomach or in the intestine (no matter of what nature), we frequently found opposite it a local peritonitis. In the peritoneal covering there was a thickening, circumscribed and distinct, which in recent cases was rather soft and accompanied by vascular injection. In old cases the original cell proliferation had undergone organization and hardening, and the thickened spot was gray or whitish, and hard. It had lost its elasticity, and was very apt to burst under a moderate amount of pressure, thus leading to perforation. In the midst of apparent health intestinal perforation would often set in, and death ensue within a day; and at the autopsy the physician would learn that the patient had been the victim of the perforation of the cicatrix of a typhoid ulceration, perhaps contracted a dozen years previously.

The diagnosis of chronic peritonitis was frequently missed. Unsuspected adhesions often existed around tumors, movable kidneys became fixed, intestines became glued together, all without recognizable symptoms. In chronic peritonitis respiration was not necessarily accelerated, and particularly was this the case in pelvic peritonitis, perimetritis, and pericystitis. There might be occasional vomiting, especially where there happened to be an intervening acute catarrh; but there were other conditions, as, for instance, renal and biliary colic, which were more liable to exhibit this symptom, and to an excessive degree. It was often entirely absent, and even in many acute cases of peritonitis it was not met with. Constipation was frequent, but diarrhœa was not unusual. The horizontal position was often quite uncomfortable; but a common colic, depending on gas not absorbed or expelled, also caused drawing up of the knees. It was, however, when the horizontal posture was shunned in chronic peritonitis that the patient was more apt to remain quiet with raised knees than one who was suffering from flatulency, where the limbs were generally tossed about continually. While the abdomen was apt to be tumid, it was to be remembered that general adiposity is most fully developed in this region; that women who have borne children are liable to have a large and prominent abdomen; that the abdomen of a healthy infant is so large as to measure one-third of its whole length; that a simple hysterical dilatation and inflation may simulate the tumefaction resulting from peritonitis; and that there may occur a local dilatation of the intestine from habitual constipation only. Moreover, in hysteria there was sometimes met with an œdematous swelling of both hypogastric regions, which would complicate the diagnosis still more seriously.

The surface of the abdomen exhibited nets of dilated veins more frequently in peritonitis and hepatic diseases than in any other conditions. Inspection might also reveal solitary convolutions rising above the level, and palpation and percussion might lead to the discovery of exudadations of various sizes and shapes, nodules, loops, and cakes, which may be either hard or soft, and which are either organized material, thickened omentum, or intestines glued together. Fluctuation would show the presence of fluid more readily than percussion, which might fail in this, that there might be adhesions between the parietal peritoneum and intestine in the flanks. The gas contained in the adherent bowel would yield the tympanitic percussion-note although the region might be filled with fluid. A change of position from one side to the other, or from the horizontal to the vertical posture, or *vice versa*, might contribute to dispel the doubt.

A chronic peritonitis was sometimes diagnosticated in the following manner: The patient is on his back, with the extremities now extended, and now flexed. Pressure is tried, soft or hard, sudden or gradual, superficial or deep, in the usual way. According to the seat of the pain experienced, inflammation or adhesion is made manifest. In many cases, however, the following manipula-

tion answers best: With the palm or finger deep pressure is first made. Perhaps there is no pain. Relieve the pressure suddenly, and a local, very distinct and circumscribed pain may be felt. Repetition of the experiment will always give the same result; the symptom being elicited by the sudden change in the relative position of the bowels. Not only pain, but the presence of hard, floating exudations can be distinguished by this and similar manœuvres.

Every change in the relative position of the bowels might give rise to pain. A sharp pain after a full meal might point to adhesions of the stomach; three or four hours after eating, to chronic colitis; a quickened inspiration or a cough, to perihepatitis; pain toward the end of micturition, to pericystitis. Pain, of varying degree and persistency, was a very frequent symptom in chronic peritonitis. Its variability depended often on the degree of irritation or congestion present, and acute attacks were frequent when there was a cause for exacerbations. The seat of the pain varied with the location and the extent of the lesion. Extensive peritonitis in the pelvis might not give rise to pain, except such as resulted from defecation, sexual intercourse, or micturition. The pain attending pericystitis was quite characteristic; appearing when the urine had been about one-half voided. In this, however, it resembled the spasmodic pain of vesical catarrh, with the exception that it was more localized above the pubes, and manifested itself more readily by pressure.

In some cases the pain of chronic peritonitis could not be diagnosticated from the enteralgia produced by other causes, such as abnormal contents, fermentation, and flatulency. Indeed, the anatomical causes of chronic peritonitis gave rise to these very conditions, for by it the intestinal movements were retarded, and from it there might result stenosis, and also twisting and adhesions; and through them any function was seriously interfered with.

The results of chronic peritonitis were very various. A simple attack of acute exudation might shape the whole future of the patient, and the histories of previous acute attacks were often not remembered. A few years ago an eminent physician and surgeon in New York died of peritonitis occurring during convalescence from typhoid fever. He had often complained of enteralgia and occasional attacks of diarrhœa during the twenty years that Dr. Jacobi had known him, but it was only just before his death that he recalled having suffered from peritonitis thirty years previously. At the autopsy there were found discolorations of the serous membrane in many places, and degeneration, dilatation, and atrophy of the colon to such an extent as to result in a number of perforations. From such a case it became evident that the most extensive adhesions and other changes might occur without any known history whatever.

The concluding portion of the paper was devoted to an exhaustive consideration of the important form of chronic peritonitis known as tabes mesenterica. The main symptoms common to every form and case of this were atrophy and tumidity of the abdomen, and the emaciation reached a degree scarcely met with in any other morbid condition. The variety of symptoms belonging to tabes pointed distinctly to different morbid processes. The gradual beginning, slow and feverless course, with but little disturbance of the bowels and other organs; the connection with a severe form of enteritis, continuation of diarrhœal discharges during the beginning and growth of tumidity, and moderate or high temperatures during the course of the morbid process; and the tumidity of the abdomen, with emaciation following chronic cough and repeated attacks of pulmonary catarrh, and terminating either in fatal exhaustion or acute peritonitis, appeared to prove that there are several distinct forms of tabes, depending on different causes, and attended with varying anatomical alterations. Thus it was evident that the former belief, that patients die of tabes through starvation, because the lacteals are no longer able to take up from the food a sufficient supply of nutrient matter, was no longer tenable.

Besides the simple secondary hyperplasia of the mesenteric glands resulting in obstruction, and the tubercular infiltration terminating in the same disturbance of function, there was a third condition which led to the symptoms recognized as belonging to tabes mesenterica, viz., chronic tubercular peritonitis. While the child was emaciated, sometimes to a fearful extent, the abdomen was tumid and elliptic, its surface shining, the superficial veins dilated, and the umbilicus expanded and flattened. There was sometimes ascitis, and sometimes hard and circumscribed tumors or intestinal convolutions might be distinctly felt or seen. There might be colic and diarrhœa, or these might be absent. The temperature might be normal. This condition might last for many months, even a year. It was capable of vast improvement, and might yield to practical recovery, though with a low standard of vitality. This capability of recovery, with which the experienced practitioner and pathologist had long been acquainted, had now and then surprised the surgeons who opened the abdomen on a mistaken diagnosis, found tubercular peritonitis, sewed it up again, and concluded when the patient recovered that this was because, and not in spite of, their uncalled-for operation. At the present time, however, we were justified in the belief that only those cases of chronic peritoneal tuberculosis will have a chance of recovery which are local, and not the result of general tubercular infection.

The diagnosis of tubercular peritonitis, or peritoneal tuberculosis, was apt to be quite difficult, and there were many chronic cases which could not be differentiated from non-infectious peritonitis and simple inflammatory processes. There were, however, cases of tumid abdomen, with atrophy of both an acute and chronic character, in which the nature of the affection could be made out with some degree of certainty. When the distention of the stomach appeared after an intestinal catarrh, when it continued after the diarrhœa had ceased in frequency, when the temperature remained high, and the symptoms (occasionally) exhibited a "typhoid" character, the existence of an acute attack of tubercular peritonitis was probable. This diagnosis was rendered the more probable by the presence of some other symptoms, although mistakes were possible even then. Among them were cough, pulmonary symptoms or dulness over the manubrium sterni, or below one or both clavicles (pointing to swelling of the tracheal or bronchial glands), a concomitant history of tuberculosis in the family, and a more intense degree of emaciation than the short duration of an intestinal catarrh would account for.

The prognosis of so-called tabes mesenterica was always uncertain except in the very worst cases. It was absolutely fatal when there was peritoneal and glandular tuberculosis complicated with or depending on generalized tuberculosis. In cases where the diagnosis of a non-infectious hyperplasia of the mesenteric glands could be made out it was decidedly more favorable. When the diagnosis of chronic peritoneal tuberculosis had been made the case was less promising; still, the possibility of recovery, or partial recovery, was not excluded.

### DISCUSSION.

DR. FRANCIS DELAFIELD said that the paper was a most timely one, and that there were few morbid conditions of greater clinical interest than chronic peritonitis. It was an affection constantly coming up for diagnosis, and as many mistakes were made regarding it as about any other with which he was acquainted. He had been accustomed to look at the disease with reference to the anatomical conditions present, and hence divided the cases into three classes: *first*, those in which there were simply adhesions of connective tissue; *second*, those in which there were present both adhesions and fluid, either serous or purulent; and *third*, those in which

there was diffuse thickening with fluid, but without adhesions.

In the first class of cases the condition was often not recognized until it was revealed by an autopsy. The symptoms often corresponded very nearly with those met with in what is known as "irritable colon," and it was very difficult to distinguish between the two. In many cases it was also difficult to distinguish it from tubercular peritonitis, when, in addition to connective-tissue adhesions, there was present a large waxy liver. Still another condition with which it was likely to be confounded was dilated pylorus, in which the stomach felt to the touch almost precisely like a mass of intestines matted together. Pain in different parts of the abdominal cavity gave the physician as much trouble as anything else in the way of making a diagnosis, and there was, in fact, very little to distinguish the pains due to different causes from each other.

In the second class of cases, where there was fluid in addition to connective-tissue adhesions, it was often difficult to distinguish the affection from tubercular peritonitis, and the diagnosis between it and carcinoma was also difficult. Again, we were likely to be puzzled by the shape which the peritonitis took. Thus, in certain instances, fluid was met with in different parts separated by partitions, and there were the physical signs of a solid tumor with fluid. What seemed like a tumor, however, was simply the intestines matted together.

In the third class, where there was diffuse thickening with fluid, but no adhesions, it was difficult to distinguish the condition from tubercular peritonitis, from multiple cancer, and from cirrhosis of the liver. Especially was it hard to diagnosticate it from the latter when the capsule of the liver was involved, since we were apt to have the gastric symptoms and the vomiting of blood, which were so often met with in that affection.

Dr. William H. Thomson also spoke of the extreme difficulty of diagnosis in chronic peritonitis, and stated that personally he had scarcely ever made the diagnosis of this disease without the mental reservation that the condition present might be something else. He recalled, however, two cases of cancerous peritonitis which had one feature in common, which he thought might be of service in other cases in making the differential diagnosis between this variety and tubercular peritonitis. The first was a lady, past forty-five years of age, who presented the symptoms of ascites. She complained of severe abdominal pain at times, but had no elevation of temperature. The special feature of the case to which he wished to call attention was the remarkably low percentage of urea present. The urine was also of low specific gravity. In this patient the autopsy showed the presence of carcinoma of the peritoneum. Much of the pain of which she had complained was referred to the left side, and this was explained by the fact that two of the false ribs were involved in the disease. There was also granular contraction of the kidneys, but this condition was not at all marked.

In the second case there was the same low percentage of urea in the urine; but here there was no trouble with the kidneys. As strengthening the diagnosis, there was a family history of cancer. In this case there was present one condition which occurred not infrequently in carcinoma of the peritoneum, viz., a distinct ridge extending across the abdomen, due to cancerous infiltration of the omentum. In cancer of the stomach Germain Sée had pointed out one diagnostic sign of some value—tenderness and enlargement of the post-clavicular glands—and Dr. Thomson said he had found this condition also present in cancerous peritonitis. The diagnosis of tubercular peritonitis might possibly be made out by the fact that in this affection the urea did not become diminished, as in cancer. Again, in cancerous peritonitis there were not the same fluctuations in temperature that were noted in the tuberculous form.

As to tubercular peritonitis he had seen one case, in a young man, in which there was distinct redness about the umbilicus, a sign of this affection to which Wilks had called attention. When ascites was present in chronic peritonitis it rendered it very difficult to distinguish between this condition and cirrhosis of the liver, and this was notably the case when the history pointed to perihepatitis. The previous history of the patient, as to habits, etc., however, would generally throw some light on the question whether cirrhosis of the liver was present or not. It was a difficult thing to account for many of the cases of chronic peritonitis, and some of them, he thought, appeared to justify the use of the term idiopathic as nearly as any affections we had to deal with.

Dr. L. Weber said that in an obstetrical case which he had attended many years ago he had had great difficulty in extracting the child, and after delivery he found that it was the subject of subacute peritonitis, and that it had been dead for a considerable time before birth. In this case the cause of the peritonitis was unquestionably syphilis. Another child, three months old, which he was called to attend, had almost from birth presented from time to time all the symptoms of peritonitis, and at the end of the third month it died of this disease. Here also the cause of the trouble was syphilis, and the child had, in addition, other well-marked signs of hereditary syphilis. Five years ago he attended a girl, seven years of age, whose family history was not good, the members of the family showing a tendency to tubercular meningitis. She had developed chronic peritonitis, and in the course of a year the abdomen had become considerably enlarged. There was ascites as well as thickening, and the patient was much wasted. By the prolonged use of the hypophosphites and cod-liver oil, and removal to the Catskill Mountains, the fluid and tenderness were got rid of, and the chronic diarrhœa from which she was suffering was cured, and the last time that Dr. Weber saw her she was entirely well.

In abdominal cancer, he went on to say, we had all seen chronic peritonitis, and it was also met with in connection with parasitic troubles, such as hydatids of the liver. He had never seen a case of chronic peritonitis, however, which was not of an infectious nature. The cases described in the earlier part of the paper he would look upon simply as cases where there had previously been acute peritonitis, with its consequent results. Of these, adhesions were the most frequent, and they often had the effect of impeding the functions of the abdominal viscera. He had no objection to calling such cases chronic peritonitis, although personally he did not consider them as true instances of this affection, like the cases to which he had referred. They were not cases of general chronic peritonitis, but exhibited simply the results of adhesions caused by the acute disease, and when in such cases a fatal result occurred, the patient really died of acute peritonitis due to perforation.

As to tabes mesenterica, he believed that this was always a tuberculous affection, and he had been much interested in the reports of the favorable results which certain surgeons had obtained in this disease by opening the abdomen and dusting the affected parts with iodoform. He had not personally had any experience with this method of treatment, but from what he had read of it he thought it would probably prove a valuable addition to our resources in suitable cases of the disease.

---

Partial Obesity.—This pathological symptom has lately been dealt with by Dr. Bollinger, of Munich. In his memoir on the subject he describes the case of a man, forty-five years of age, who had served all through the Franco-German War (1870–71), and who for the last six years had suffered from *partielle Fettsucht* (partial obesity). The cheeks, the chin, the throat, the thorax, and the upper arms exhibited accretions of adipose tissue quite morbid in their excess. The patient could not account for it, as he had lived sparingly, had inherited no tendency too obesity, and had transmitted the same to none of his children, twelve in number. Dr. Bollinger finds the disease to be more common among men than women.—*Lancet.*

## OUR LONDON LETTER.

(From our Special Correspondent.)

THE HARVEIAN ORATION AT THE COLLEGE OF PHYSICIANS—THE SOCIETIES—DR. HUGHLINGS JACKSON ON THE RELATIONS OF OPHTHALMOLOGY TO GENERAL MEDICINE—SIR ANDREW CLARK ON THE NON-TUBERCULAR AND NON-CARDIAC HÆMOPTYSIS OF ELDERLY PERSONS—THE MEDICAL AND CHIRURGICAL SOCIETY—ACUTE LEAD-POISONING—ALPINE CLIMATES FOR PHTHISIS—FORMATION OF A FUND TO ASSIST SUITABLE CASES—THE ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION IN 1890—THE LIBRARY OF THE COLLEGE OF SURGEONS.

LONDON, October 26, 1889.

THE Annual Harveian Oration at the College of Physicians was delivered last week by Dr. James Pollock. A series of successive annual addresses on the same subject must necessarily present strong points of resemblance. To strike out in any original vein of thought becomes, in fact, more difficult with every succeeding orator. On the present occasion the usual account of Harvey's work was given, together with the inevitable remark that, although Italian investigators did much, yet it was by Harvey that the actual mode of working of the heart was experimentally demonstrated. Harvey's task would have been impossible without vivisection, and there were few animals which he did not thus examine. He was the greatest exemplar of vivisection, if he were not its originator. But if great observers had not arisen after him, both medicine and surgery must have remained stationary. Dr. Pollock then skilfully pointed out how later discoveries had added to and completed the knowledge obtained by Harvey, without which, however, they would have been impossible. The researches and discoveries of Lavoisier, Priestley, Laennec, Stokes, Corrigan, Latham, and Williams were briefly referred to. The elucidation of the mechanism of the circulation enabled us to understand the action of the heart in disease.

Referring to modern advances in pathology, Dr. Pollock said it had been asked, what effect had all our improvements in medical science had on the general health of the country? He answered this question by showing from statistics that a marked decline had taken place in the death-rate in recent years, and that by far the largest proportions of the years added to human life in England were lived at those ages (between twenty and sixty) at which the value of life to the community was greatest. Since the passing of the Health Acts the mortality from phthisis had greatly lessened, and his own experience was that the duration of life in those suffering from phthisis had become distinctly prolonged. There was a slight increase of mortality (from all causes) at the more mature periods of life (among males of thirty-five and upward), but this was small and was becoming less; it was counteracted by the increasing number of the younger who now arrived at adult life. This slight increase in adult mortality might be brought about by the cares and worries of our higher civilization. Dr. Pollock remarked that his audience knew well what part of the organism it was which generally failed under pressure. The public said it was "brain," but they knew that it was "heart"—the motor power which Harvey studied, though perhaps he did not foresee to what pressure a modern civilization and struggle would subject it.

The medical societies have now commenced work for the winter session. The first meeting of the Ophthalmological Society was held last week, when a presidential address on "Ophthalmology and General Medicine" was delivered by Dr. Hughlings Jackson. Dr. Jackson remarked that no department of medicine had greater attractions for him than ophthalmology, and he still thought what he said in his address to the Medical Society in 1877, viz., that it was the luckiest thing in his medical life that he began the scientific study of his profession at an ophthalmic hospital. At an ophthalmic hospital one had the opportunity of being well disciplined in exact observation. When a physician saw how carefully and precisely ophthalmic surgeons investigated the simplest case of ocular paralysis, he was getting a lesson in exactness, and would be less likely in his own department of practice to deal in such generalities as that a patient's seizure "had all the characters of an ordinary epileptic fit," and more likely to take pains to describe the convulsion, the place of onset, the march, and the range of the spasm. Since six cranial nerves and the sympathetic nerve supplied the eye and its apparatus, it was evident that without a good knowledge of eye diseases the thorough investigation of many morbid affections of the nervous system could not be carried out. It was not many years since the ophthalmoscope was rarely used except by ophthalmic surgeons. Dr. John W. Ogle was the first physician in this country who used the instrument in the investigation of medical cases. It was very unlikely that there was to-day a single patient in the National Hospital for the Paralyzed and Epileptic whose eyes had not been examined by this instrument. Dr. Jackson then gave numerous illustrations of the relation of ophthalmology to neurology. He remarked that of course it had much wider relations, and concluded by quoting the following words from a paper by Dr. James Anderson: "It seems to me the best and most hopeful feature of ophthalmology that it has relations, closer or more remote, with every branch of medicine and surgery—indeed, with almost every branch of science."

The Medical Society of London and the Medical and Chirurgical Society have held their first meetings during the present week. At the former, after the delivery of an inaugural address by the President (Dr. Theodore Williams) Sir Andrew Clark read a paper on the "Non-tubercular and Non-cardiac Hæmoptysis of Elderly Persons." He related in detail two fatal cases of hæmoptysis occurring in elderly arthritic patients. In both cases the absence of tubercular, malignant, or cardiac disease was proved by post-mortem examination—which, however, showed that the hemorrhages were in the immediate neighborhood of patches of emphysema—and that the minute vessels, the terminal arteries for the most part, were in those localities always diseased. Sir Andrew said that plainly enough the source of the hemorrhage lay in the diseased blood-vessels, and probably the disease was of an arthritic nature. Since 1875 he had seen in persons over fifty years of age some twenty cases of this form of hæmoptysis—a variety of which he had been unable to find any clear account in the annals of medical literature and which he ventured to call "arthritic hæmoptysis." The cases he had related had led him to discontinue the ordinary method of treatment of hæmoptysis by astringents, and to try another method which seemed more rational and which he had hitherto found successful, viz., rest and warmth, a light and rather dry diet, counter-irritation to the chest, a succession of small doses of calomel at bedtime, supplemented by saline aperients in the morning, and the taking between meals, twice or thrice in the day, of a mixture containing iodide of potassium, bicarbonate of potassium, and ammonia. Sir Andrew Clark then related two illustrative cases thus successfully treated. In one, the bleeding recurred but was quickly cured by calomel and salines.

At the Medical and Chirurgical Society an inaugural address was delivered by the President, Sir Edward Sieveking, in which he traced the history of the Society from its foundation in 1805 to the present time. Dr. Thomas Oliver, of Newcastle, then read a paper on "Acute Lead-poisoning," which was followed by an animated discussion.

The value of Alpine climates in certain cases of phthisis has long been before the profession. Unfortunately,

many of the patients most likely to benefit by the climates in question are precluded from trying them owing to want of means. It is, therefore, gratifying to find that a fund has been formed for the pecuniary assistance of such cases. Drs. Symes Thompson, Theodore Williams, and William Ewart, have undertaken to examine cases and decide as to their suitability on medical grounds.

Birmingham has been selected as the meeting-place of the British Medical Association in 1890. Birmingham may justly be described as a stronghold of the Association, or, rather, of those who support the present policy of its Council. The latter could not have shown their weakness more conspicuously in the present crisis than by determining to hold the next annual meeting in that town.

The library of the College of Surgeons is to be kept open till 9 P.M. on five evenings a week until the end of the year. Should the experiment be appreciated by a large number of readers, the extension of hours will no doubt be made permanent.

## BOTH RIGHT AND BOTH WRONG.

To the Editor of The Medical Record.

SIR: Paradoxical as the above caption may appear, it will, nevertheless, be found correct when applied to the facts and arguments adduced pro and con in reference to artificial anæsthesia during sleep, as published from time to time in THE MEDICAL RECORD and other journals of late years. Many cases have been published, where the effort to produce chloroform anæsthesia during sleep was most successful; while on the other hand, perhaps a still larger number resulted in failure.

Any amount of negative evidence, however, cannot break the force of one well-attested, positive case, much less that of many. So, it remains to be explained why some succeed, and why others fail; which, no doubt, is easy enough when all the factors are considered, and to each its intrinsic importance is allowed. The proper understanding of this difference in the results of the investigation of medical men of equal attainments, is not only of much interest to therapeutic medicine, but it is of the greatest importance viewed from a medico-legal standpoint, since cases will continually arise wherein medical evidence is liable to be very conflicting, much to the damage of justice, and quite humiliating to professional pride. It is a well-recognized fact that some persons are of a phlegmatic temperament, and consequently are not impressible in a high degree, through the special senses, to the various external agencies surrounding them. Their feeble respondence to external agents during all their wakeful moments, proves this to be true, and it holds equally good when they are overtaken by sleep. Hence, a person so constitutionally disposed would be more likely to come under anæsthesia by inhaling medical agents during sleep, than others of a different or opposite predisposition. The experiment tried on such persons, and under the most favorable circumstances, would not be likely to be disappointing.

On the contrary, the very opposite would naturally be expected from a person in whom the nervous system is wrought up to a high degree of tension. In wakeful and sleeping moments, alike, a respondence to impressions from every source is so acute as to be next akin to the morbid element. The repose of such persons is more of a slumber than deep, sound sleep. A state absolutely of hyperæsthesia, both as to touch and sound, exists in persons thus constituted. Some of them are so sensitive to external agents as to be awakened by another person, especially if a stranger, on approaching close to the bedside, although ever so stealthily. Now, in a case like this, under the ordinary state of being, doctors alive to such influences would hardly expect, beforehand, to succeed in producing anæsthesia during sleep; if so, the subject would surely wake them to a realizing sense of their mistake. These two opposite states of the constitutional make-up, found existing in every community, offer a good explanation of many successes and failures in an effort at anæsthesia, thus harmonizing to a certain extent experimentation in this direction.

Again, while the majority of persons are free, perhaps, from such pronounced tendencies, they are inclined more or less to the one or the other, besides being influenced by many other considerations, either favorable or unfavorable in such an experiment.

One who had undergone great fatigue during the day would be less likely to wake on the administration of chloroform, especially if the supper had been light, and it was in the midst of the first sound nap; the opposite state of things existing, would of course favor wakefulness. Owing to habit formed, many persons are easily awakened, the slightest noise being quite sufficient; and, as a matter of fact, it would be next to impossible to bring them under anæsthetic influence. Most people, especially if fatigued, sleep soundly about midnight, and at that time would be less likely to wake on receiving an anæsthetic.

Whatever tends to make one restless—such as overheating, mental anxiety, pain, or hyperæsthesia from rheumatism, and insect annoyance—would naturally render a subject unfit for experiment, because sleep is not sound enough. Persons who, but just before receiving the anæsthetic, have, from any cause, been deprived of a large amount of sleep, would be more difficult to wake, because of that fact; and therefore, much easier to anæsthetize while thus thoroughly lost to all sense of their surroundings. Sleeping with one eye open would not apply in their case. The experiment would be less likely to succeed in persons laboring under acute or chronic ailments, for usually all such have their slumbers to rest on them lightly. With children, as might be supposed, the chances of success appear to be much better. This is accounted for from the fact that children are more susceptible to medical impressions than adults; and furthermore, they sleep sounder and with more perfect abandon when there is no disturbing cause. More sleep is required by them than older persons, unless the very old; so that when they round up the day's exercise and excitement, tired nature is quite ready to fall into the welcome embrace of soothing Morpheus.

As an illustration of how it acts with children, the case reported in THE MEDICAL RECORD of September 7th, by Dr. Theodore Potter, is fairly representative. This child had been on the go all day, when he received the injury; and nature was then still further exhausted and undone, by ceaseless efforts to find relief from pain, for two hours, at which time, 9 P.M., the limb was placed in comfortable position; after this, all things favoring, the patient soon found relief from suffering and exhaustion in deep sleep, from which chloroform inhalation to anæsthesia, even, did not arouse him. Doubtless, had this occurred in the forenoon, anæsthesia would then have been far more difficult, if not impossible, to effect, for the reason that sleep would not have been needed, and it would be out of the regular order of physiological rest. In most cases, an injury of like character, no doubt, would interfere with success; but in this instance, the injury occurring when the day was fairly on the wane, and the limb having been made comfortable, it seems not to have militated against a favorable issue. Because of greater pleasantness, and more concentration, it can hardly be questioned that chloroform will be found to succeed better in such attempts than other articles possessed of like properties. Doubts seem to exist in the minds of many, both lay and professional, as to whether it is possible for burglars and others criminally inclined, to effect successfully artificial anæsthesia on their intended victims during sleep. When it is taken into consideration that they ply their vocation usually about midnight, just the time the subject upon whom the experiment is to be tried, as well as all nature, is wrapt in the deepest slumber, it is not to be wondered at if they should succeed. Doctors try the experiment, as a rule, on patients afflicted with disease;

who are restless, generally, and would be liable to wake; but burglars have the very best subjects upon whom to operate, and this of itself would seem to warrant success, other things being favorable. In addition, while they may not be skilled in the administration of an anæsthetic, they have cultivated sleight-of-hand performances, and cat-like stealthiness, until advantages would perhaps be in their favor. This is a point upon which there ought to be a more unanimous conviction and expression by medical men, in order that justice may be done, and proper protection given, to the helpless while enjoying "tired nature's sweet restorer—balmy sleep." The medico-legal phase of this question, is, indeed, a most important one, and the interest therein centred will doubtless become still greater as time elapses, for all kinds of wickedness and crime seem to be fearfully on the increase. In the administration of an anæsthetic during sleep, very much depends on the manner of giving it in order that the proper effect shall be produced. That it should be given very gradually, and much diluted with air, stands to reason; and herein lies an advantage in burglarious cases, since, from their known habits of procedure, burglars would be most certain to give it in that way.

Admitting foregoing elucidations, surely a better correspondence of opinion on this question ought to be reached by the medical profession.

As to whether artificial anæsthesia applied to different people can or cannot be effected during sleep, depends on so many conditions, and such a variety of circumstances, no one can form a correct conclusion until the question has been viewed in all its bearings; and when that shall have been done by individual inquiry, doubtless professional opinion will be tolerably unanimous.

B. F. HART, M.D.

SWEET SPRINGS, MO.

## THE PREVENTION OF SEA-SICKNESS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In THE MEDICAL RECORD of September 28th appears an item, in which it is stated that "Dr. Ivan A. Mitropolsky, of Moscow, warmly recommends as a simple method for preventing or aborting all symptoms of sea-sickness," the closing of the eyes and making deep and slow inspirations and expirations. The item also states that a writer in the *London Medical Recorder* intimates that this means is not original with Dr. Mitropolsky, and cites an article in the *British Medical Journal*, March 24, 1888, by Dr. Leiser, in which the writer says that sea sickness is caused by irregular and imperfect respiration, and that a system of regular free breathing prevents or rapidly relieves it. He also gives the result of various experiments, which he says were entirely successful.

In this connection, I trust that I may be pardoned for calling attention to an article entitled "A Study of Sea-sickness," contributed by myself to the *Century Magazine*, July, 1883.

It was the purpose of that article to show that "sea-sickness is the result of reflex irritations arising from little surprises to the muscles, and shocks to the nerves engaged in certain important functions." Among these important functions was included that of respiration, which was discussed at some length. I quote a few sentences:

"Another source of nervous perplexity, then, of no small consequence, will be found in the inclination to breathe synchronously with the swing of the vessel. . . . If the ship's motions were only in one direction, and if they were uniform in time, they would produce, in one sitting on the deck or reclining in a berth, the same agreeable effect as swinging on a hammock on shore; but, unfortunately, there are too many elements of disturbance in the rhythm of the ship's movements to react in such an agreeable manner. . . . When the ship rolls regularly, once in so many seconds, the people breathe regularly, but when the ship's motions lose uniformity, the irregularity of performing the function (of respiration) would be a sufficient cause for general nervous disturbance."

In speaking of the means of preventing or mitigating the evil, the article continues:

"Strict attention should be directed to the state of the respiration. Many a threatened sickness may be averted by drawing a few deep, full inspirations at regular and rapid intervals. One who is overtaken by sea-sickness while lying quietly in the berth in the darkness of the night, may be quite sure that he or she is breathing in the same unsteady manner in which the ship is moved upon the water. If the sufferer, at the first premonition of sickness, would rouse sufficiently to attend properly and earnestly to the breathing process, it is probable that the nausea would pass away as suddenly as it came. Under all circumstances, then, the breathing should be strictly dissociated from the motions of the ship."

It has not been my purpose to quote at any length from the article referred to, which treats the subject upon broader principles than either of the articles quoted by THE MEDICAL RECORD, nor to refer to any other of the disturbances arising in the performance of several functions which were recognized as causative in this malady. My purpose has been only to call attention to the similarity of the views of these writers, so far as this function is concerned, to those published in a widely circulated periodical more than six years since.

GEORGE T. STEVENS.

33 WEST THIRTY-THIRD STREET, September 30, 1889.

## A MEDICAL EXAMINING BOARD FOR NEW YORK STATE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: To those who are close observers of the drift of opinion among medical men, there can be no doubt that the question of a Medical Examining Board for the State of New York—no matter how strenuously it may be opposed by an influential minority—must soon force itself upon us for settlement.

That the Empire State and the metropolis of this continent, from which all that is progressive and wise should emanate, should remain passive, with folded hands, seemingly oblivious to the progress which other and younger States are making, is a confession as shameful as true.

Illinois, Virginia, Alabama, North Carolina, and Minnesota have done, and are to-day doing, a hundred-fold more to elevate the standard of medical education, close the door to quackery, and increase the respect on the part of the laity for our profession, than New York State with all its boasted wealth and culture, and its great didactic and clinical resources.

It was my privilege to attend recently, at Roanoke, Va., the annual meeting of the Medical Association of that State. The Board of Medical Examiners were then in session. Twenty-six applicants came before the Board for license to practise. Twenty-three held diplomas from well-known medical schools, and three were non-graduates who had attended one or more courses of lectures. Only eight of this number received the Board's permit. These gentlemen are shutting the door on what heretofore has been called medical education. Their action was unanimously approved by the State Association. This Association, by their earnest and united action, have about closed the door on quackery. If every other State in the Union would secure such a law and organize such a courageous and honorable Board of Examiners, can one doubt that within five years' time the annual number of graduates would be very greatly diminished? Those who elect the calling of medicine would be compelled to undergo thorough preliminary preparation; the standard would be raised equal to that of the best schools of Great Britain and the Continent.

To bring about this "consummation devoutly to be wished," I respectfully suggest the following:

1. Let the New York Academy of Medicine issue a call for a convention of representatives of all unsectarian County Medical Societies of New York State.

2. At such convention the representation and voting power of each society to be proportionate to its actual paid up membership, as attested in writing by the President and Secretary of each society—say, one vote to every twenty-five members or less. The votes to be by person or written proxy, and no proxy to be cast except by a representative of the society from which it is sent.

3. This convention to draft a set of rules for the better regulation of the practice of medicine in the State of New York, and elect a State Board of Medical Examiners.

Such a movement, endorsed and supported by a fair majority of the profession in this State, would become a law by act of the legislative body and the Governor. It could not be successfully resisted or thwarted in its object.

This Board to be composed of members of the medical profession qualified by special experience in the departments assigned to them as examiners.

The proposition to exclude from the Board of Examiners, professors in colleges authorized to confer a degree in medicine, is not fair; nor would it be just to permit one-half of this Board to be composed of college professors, as recently advanced in an article in the *North American Review*. There can be found enough perfectly competent material outside of the colleges to organize a dozen examining boards. It would be a fair division, in my opinion, if one-fourth of the entire Board selected by the profession in the State were college teachers.

The Board of Examiners should consist of two members for each of the following departments: Anatomy, physiology, chemistry, materia medica, therapeutics, medicine, surgery, obstetrics and gynecology, and pathology, sixteen in all. The examinations should be written, oral, and practical. A candidate should be satisfactory in seventy-five per centum of the grading in each branch. Failing to secure this minimum in one-half of all subjects, he should be rejected. Failing in less, that he be allowed within six weeks a second examination in the branches in which he was found deficient. Failing a second time, he should be given one year for a final examination. A fee equal to the ordinary "graduation fee" of the colleges to be charged each applicant. The amount received to go to defray the expenses of the Board.

The question of qualification to be the chief consideration in determining the issue of a permit. All applicants to be given an equal showing, without question as to the college from which they hail or the school in which they propose to practise.

In voting upon the subjects of surgery, medicine, and obstetrics and gynecology, the affirmative vote of both examiners in each branch should be required. In the five other departments one affirmative vote in each may secure a permit, giving eleven out of sixteen votes as the lowest possible vote. The above to go into effect when the "Rules for the Better Regulation of the Practice of Medicine in the State of New York" should become a law.

There are many minor points of interest which might be added, but I do not wish to impose further upon your valuable space. It does seem to me that the Academy of Medicine, were its vast influence concentrated in the movement, could not only bring about the organization of the State Board, but go farther and secure the endowment and support of a medical college on a grand scale, in which the requirements for a license to practise should be three full years of didactic and one year of strictly clinical work.

JOHN A. WYETH, M.D.

## DETERMINATION OF SEX.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Few things are to me more interesting than a muddle, however "deplorable" it may appear to a man in Siam. In your issue of September 21st, Dr. Thompson writes from Siam like a man deeply impressed with the importance of his theme, and thereby enlists my deep sympathy, and draws me away for the time from the company of those serene but simpler souls who are content to view the subject as one of the hidden mysteries of nature.

Dr. Thompson is willing to part with the old superstition that the right testicle begets boys and the left one girls, and leaves the impression that with a little persuasion he would dump into the same waste the theories that boys are begotten before, and girls after midnight; that it depends upon the relative ages of the parents; that it depends upon their relative vigor; upon whether begotten before or after menstruation; upon the preponderance of amatory desire. With regard to the last, however, he would evidently hear argument, for he asks, with touching pathos, "Why the silence of medical men in regard to it?" Why, indeed?

I will speak of things about which I have no doubt, remarking, by the way, that doctors pick up a good many things which do not concern them personally. A. had amativeness well developed. B. had no sexual feeling whatever. Their ages differed by one year. After long resistance B., being left alone by the death of her parents, yielded to A.'s suit and married him. She accepted with Christian resignation all the burdens of wifehood, but the sexual act never produced in her any other feeling than aversion and disgust. Yet she bore children somewhat rapidly, in this order: Girl—boy—girl—boy—girl. After the last birth, incensed at her husband for whipping one of the children, she withdrew from her husband's bed till the day of her death, but discharged all the other duties of wife and mother with dignity and fidelity.

It is not germain, but may be of interest to speak of the children of this union. The eldest daughter, after much importunity and repeated refusals, finally consented to marry an eligible gentleman. She made a gentle and agreeable companion, yielding all that her husband demanded, experiencing neither pleasure nor disgust from his embraces. But she would sometimes laugh immoderately at the most critical periods of his career, recalling to his memory our old friend Shandy and his clock at most inopportune moments. His intense interest in passing events was wholly inexplicable to her. She early conceived, but, unfortunately for this tale, died of uræmic convulsions a month before term, and the sex of the fœtus was not made manifest. The youngest daughter was an enigma. Without apparent effort on her part to please, men "fell at her feet," almost as a matter of course. But she would have none of them, and, after rejecting suitor after suitor, was gathered unto the angels, where she belonged. The boys, like their father, possessed normal amativeness.

C. was thrice married, to girls three, five, and fifteen years, respectively, younger than himself. Two of the ladies may be ranked as normal, with regard to sexual feeling, the other at zero. The result was male children only in each case. But "it is well known," continues Dr. Thompson, "that an intimate relationship exists between the physical and psychical condition of the parents, and conditions or characteristics of the offspring. Is it too much for us to believe that on the line of this relationship may be found the determining factors of sex?"

I fear it is. An old German farmer and his wife had no psychical conditions that were visible on the surface. They needed boys for the farm and ought to have had them; but the result of their love was nine healthy girls. A neighbor said to the old lady in my presence: "Why didn't you turn the bed around? I have heard that that would change the luck." Her innocent reply was: "I did durned it, and durned it, and durned it, until, bless God, the gude man could git neider gal nor poy!" But there are compensations in nature. A neighboring couple had a similar family, all boys, and no amount of praying and bed-changing would change the luck.

But I am not accustomed to discuss a subject without settling it. On one occasion in my student days the Pro-

fessor of Obstetrics devoted a whole hour to the question, "Why does labor occur?" He reviewed the speculations of authorities from the time of Hippocrates down, and left the question precisely where he found it. After the lecture, in a spirit of flattery no doubt (I had paid for all my tickets in advance), he asked if I had formed an opinion on tne question. "Why, Professor," said I, "there is no room for any question about it. God made woman and subjected her to the operation of certain natural laws. She conceives, gestation proceeds until the time of Nature is accomplished; then labor begins because the woman can't help it!"

Why not apply the same rule to the question of sex? Where is the objection to the hypothesis that sex is inherent either in the ovum or in the spermatozoon which finally impregnates it? We may, then, reasonably infer that in the ova of one female, or the sperm of one male, one sex predominates and the other in another; and that the result of copulation in a given case is purely a matter of chance, if we exclude Omniscient decree in matters of such detail. This, it seems to me, would be a satisfactory solution of the "deplorable muddle."

S. S. TURNER, M.D.,
*Acting Assistant Surgeon U.S.A.*

## PROTECTION FOR RAILWAY TRAVELLERS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: "Missouri," in your issue of September 28th, does well in calling attention to the exposed condition of the "closet" department of sleeping, parlor, and other styles of railroad cars. But aside from the danger specified—direct exposure to the inrushing cold air—there are other dangers; those caused by the horribly cold surroundings in the box, where one must be penned for the time being; the lump of ice in the urinal opposite, for one to stare at while perched on the seat does not add materially to the comforts, unless as a "peristaltic persuader" of the unfortunate occupant of the pen. All this needs to be, and must be remedied; and "Missouri" has acted wisely in taking advantage of the columns of your valuable and widely circulated journal, as it does not "advertise" "the few new cars for special exhibition."

Since the subject of railroad car closets has been broached, it will not be amiss to call attention to other dangers, aside from those mentioned. These "conveniences" (?)—inconveniences and death-traps more properly—play, I believe, a considerable part in the cause of local outbreaks throughout the country of typhoid fever. There are in this land of advancement but few water-supplies providing drinking water for our large towns and cities that are not in constant danger of being polluted by typhoid or other forms of specific germs—cholera if it were prevalent. These germs are dumped along the roadbeds of the many railroads that are constantly winding about the streams of our water-supplies, or, it may be, crossing them at some or many points along their course. This is especially liable to occur where roads are largely engaged in the transportation of emigrants. It is to be hoped that these abuses, of railroad travel may be done away with. Perhaps in no surer way could they be remedied than by calling to them the attention of the newly formed Association of Railway Surgeons, from which so much good is bound to come in the hope that many other dangers to which human life is now subjected may be removed.

For my own part, I feel that the house-trap and closet of most recent design should be placed in all railway cars; these to be connected with pipes that would conduct the flushing water, with the excrementitious materials, along to the fire of the engine, where they can be run through a convoluted system of pipes exposed to the intense heat of the fires before being discharged to the earth, when they will have been rendered innocuous.

RICHARD H. GIBBONS, M.D.

435 WYOMING AVENUE, SCRANTON, PA.,
October 1, 1889.

## EATING BEFORE SLEEPING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a recent issue of THE RECORD I notice an article on "The Food Treatment of Insomnia," by Dr. Eggleston. There is much truth in what he says.

Very often when at the Asylum I have seen patients who had long refused food and been sleepless before admission (notwithstanding that large doses of powerful hypnotics had been given) going quickly to sleep after having been fed with the stomach-pump.

Dr. Eggleston seems to think that there is some excuse for the old saw of "not eating before sleeping," for he says, "it may be true that digestion goes on more slowly during sleep."

Now there is really no excuse for the old prejudice, and we are only able to sleep well without first eating (especially if hungry) by long training in rebellion against nature. For is it not a fact that the stomach requires more blood during the period of digestion, and what more natural, then, than that the blood be drawn from the brain, as it is the most vascular organ of the body, and during sleep less blood is required in the brain? Hence digestion should aid sleep, and sleep aid digestion.

Common observation of the lower animals all goes to show the same that the doctor points out with babies; that to eat first and sleep afterward, is nature's rule and their practice.

As the exception proves the rule in many cases, so here. If one eats uneasily digested food before retiring he will very likely be disturbed in his sleep, or perhaps may not sleep. But the same things eaten prior to a season of waking hours would also have given distress.

The more busy and occupied the man, the less attention he would likely give to the distress of indigestion. So, on the other hand, at night, when he has nothing else to do but think of his pains, they naturally make more lasting impressions on him; and, of course, sleep lost is another penalty, not of having eaten before retiring, but of having eaten substances that would cause distress under any circumstances.

W. WASHBURN, M.D.

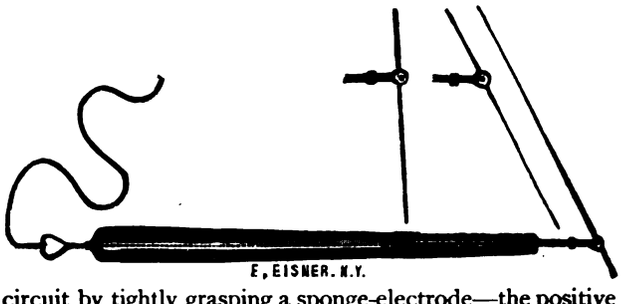
42 IRVING PLACE.

# New Instruments.

## A NEW NEEDLE-HOLDER FOR REMOVING HAIRS BY ELECTROLYSIS.

BY FREDERICK J. LEVISEUR, M.D.,
PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL AND DISPENSARY.

THE removal of superfluous hair is accomplished, as is well known, by introducing a very fine needle, connected with the negative pole of a galvanic battery, down to the bottom of the hair-follicle. The patient completes the



circuit by tightly grasping a sponge-electrode—the positive pole. After a short time, say ten to thirty seconds, the circuit is interrupted, the needle withdrawn, and the hair removed by forceps, if found sufficiently loose.

The mechanical difficulty of this simple process consists in probing the little *cul-de-sac* down to its deepest part without injuring much the surrounding tissue. A little instrument which I have devised materially facilitates, I think, this operation. It is a needle-holder modified after the following manner: The small metal point

is ball-shaped and perforated from top to bottom, as well as from behind above, to in front below. The needle can be inserted and fastened by screw arrangement in three different positions, so as to form, with the handle, a right, or an acute, or an obtuse angle. The operator, who is standing or sitting behind his patient, holds the instrument like a writing-pen. His forearm is at rest, and a slight movement of the wrist suffices to make the needle enter deeply into the hair-follicle with an easy and elastic motion. There is no place in and around the patient's face that could not easily be reached with the instrument.

The accompanying wood-cut, showing very well the principle of my new needle-holder, was kindly furnished to me by Messrs. F. Eissner & Co., of No. 18 Bible House, Third Avenue, New York, who manufacture and sell the instrument.

687 Lexington Avenue.

## A NEW GASTRIC ELECTRODE.

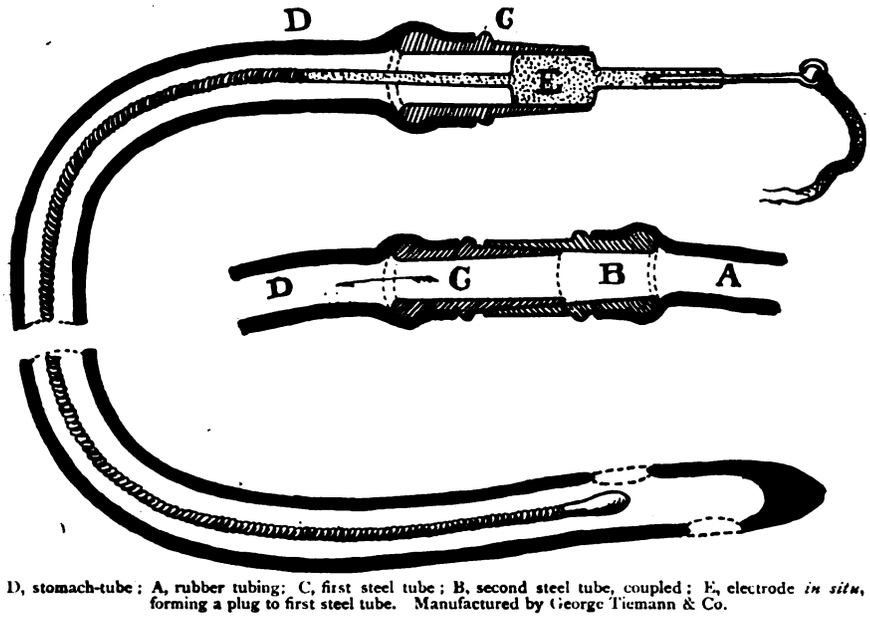
By CHARLES G. STOCKTON, M.D.,

Professor of the Theory and Practice of Medicine, and Clinical Medicine, Medical Department of the University of Buffalo, N. Y.

For the past two years I have been studying the results of the electrical currents applied by means of a gastric electrode for the relief of certain disorders of the stomach.

Numerous experiments taught me the importance of preventing the metal electrode from coming in direct contact with the gastric mucous membrane. To overcome this objection efforts were made to utilize the column of water in an ordinary stomach-tube as the conductor of the current; and it was found that, by using a saline solution in the tube, a weak current could be carried, but the method was troublesome and the results unsatisfactory.

An instrument was then made, by carrying through a stomach-tube an uninsulated wire, which at the distal end of the tube terminated in a button so arranged that it came near the fenestrum of the tube, and yet so that the mucous membrane could not reach the metal point. This contrivance overcame the internal resistance and proved effectual, but it was inconvenient to the patient, inasmuch as it was necessary to introduce an ordinary tube for washing out the stomach before the tube containing the electrode could be employed.



D, stomach-tube; A, rubber tubing; C, first steel tube; B, second steel tube, coupled; E, electrode *in situ*, forming a plug to first steel tube. Manufactured by George Tiemann & Co.

Finally, I contrived an apparatus which for some months has been used with satisfaction both by myself and others, and which seems to meet every requirement. It is admirably constructed by Messrs. George Tiemann & Co. It consists of an elastic stomach-tube twenty-four inches long, which at the proximal extremity is slipped over one end of a short steel tube. Over the other end of this tube fits a second short steel tube, making a tight joint; and to this is attached sufficient rubber tubing to make a convenient siphon. We have now an ordinary lavage tube, with a metal coupling. After emptying the stomach, uncoupling the joint, and thus removing the rubber tubing, the electrode, which consists of a spiral steel wire with an enlargement at the end, is introduced through the stomach-tube without removing it. The electrode makes a tight plug for the first steel tube, thus preventing the regurgitation of fluid from the stomach, and at the same time holding the instrument together. The whole makes an uncomplicated affair, very easily managed, and conveys a current strong enough for any purpose. It is best to have a little weak solution of sodium bicarbonate in the stomach before introducing the electrode.

The illustration is from a pen sketch by Dr. H. G. Matzinger of the Buffalo State Asylum for the Insane.

There remains much to be said about the practical results of the electrical treatment of gastric disorders. This is hardly the place to detail clinical experience, but I may be allowed to express the opinion that this method enables one to effect, beneficially, disturbances of motion, sensation, and secretion, which, in some instances, baffle other plans of treatment.

278 Franklin Street.

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 27 to November 2, 1889.*

Heger, Anthony, Lieutenant Colonel and Surgeon. By direction of the Secretary of War, so much of par. 2, S. O. 24, October 16, 1889, from this office, as relates to him, is amended to read as follows: Lieutenant-Colonel Anthony Heger, Surgeon, is relieved from further duty in the Division of the Atlantic, and will at once report to the Major-General commanding the army for duty in this city. Par. 3, S. O. 252, Headquarters of the Army, A. G. O., October 29, 1889.

Forwood, William H., Major and Surgeon. By direction of the President, is detailed as a member of the Army Retiring Board at St. Paul, Minn., convened by War Department Order dated January 12, 1889, published in S. O. No. 10, January 12th, from Headquarters of the Army, vice Captain Edgar A. Mearns, Assistant Surgeon, who is hereby relieved. Par. 12, S. O. 254, A. G. O., October 31, 1889.

O'Reilly, Robert M., Major and Surgeon. By direction of the Secretary of War, par. 3, S. O. 24, October 16, 1889, from this office, is so amended as to grant him leave of absence for six months, with permission to leave the United States, to take effect November 1, 1889. Par. 6, S. O. 252, A. G. O., Washington, D. C., October 29, 1889.

Gibson, Joseph R., Major and Surgeon. Granted leave of absence for seven days, to take effect from date of being relieved from duty at Fort Sheridan, Ill. Par. 9, S. O. 249, A. G. O., October 25, 1889.

Taylor, Morse K., Major and Surgeon, retired. Died October 20, 1889, at San Antonio, Tex.

Willcox, Charles, First Lieutenant and Assistant Surgeon. Appointment to rank from October 29, 1889.

MAUS, LOUIS M., Captain and Assistant Surgeon. Granted leave of absence for two months, on Surgeon's certificate of disability. Par. 11, S. O. 249, A. G. O., October 25, 1889.

GORGAS, WILLIAM C., Captain and Assistant Surgeon. By direction of the Secretary of War, is relieved from temporary field duty in the Department of the Missouri, and will join his proper station (Fort Barrancas, Fla.). Par. 2, S. O. 251, A. G. O., October 28, 1889.

MAUS, LOUIS M., Captain and Assistant Surgeon. By direction of the Secretary of War, so much of par. 10, S. O. 242, October 17, 1889, A. G. O., as directs him to report in person for duty at Fort Stanton, N. M., to relieve Captain Marcus E. Taylor, Assistant Surgeon, is revoked, and Captain Taylor will proceed to Boise Barracks, Idaho Terr., as directed in said order, as soon as medical attendance shall be provided for Fort Stanton. Par. 10, S. O. 249, A. G. O., October 25, 1889.

CABELL, JULIAN M., First Lieutenant and Assistant Surgeon. Granted leave of absence for two months, to take effect about November 10, 1889. Par. 7, S. O. 249, A. G. O., October 25, 1889.

MCVAY, HARLAN E., First Lieutenant and Assistant Surgeon. Appointment to rank from October 29, 1889.

FRICK, E. B., First Lieutenant and Assistant Surgeon. Appointment to rank from October 29, 1889.

BY direction of the President, the Army Retiring Board convoked at Vancouver Barracks, Washn. Terr., by War Department order dated December 15, 1888, published in S. O. 292, December 15, 1888, from Headquarters of the Army, is dissolved. Par. 1, S. O. 250, A. G. O., Washington, October 26, 1889.

---

*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 2, 1889.*

NASH, F. S., Passed Assistant Surgeon. Detached from duty in Bureau of Medicine and Surgery and ordered to the Petrel, November 14, 1889.

BOGERT, E. S., Medical Inspector. Ordered to examination, preliminary to promotion to Medical Director.

NORTON, O. D., Assistant Surgeon. Ordered to examination, preliminary to promotion to Passed Assistant Surgeon.

KITE, J. W., Assistant Surgeon. Ordered to examination, preliminary to promotion to Passed Assistant Surgeon.

STONE, E. P., Assistant Surgeon. Ordered to examination, preliminary to promotion to Passed Assistant Surgeon.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 2, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 43 | 16 |
| Scarlet fever | 38 | 4 |
| Cerebro-spinal meningitis | 4 | 2 |
| Measles | 21 | 0 |
| Diphtheria | 80 | 18 |
| Small-pox | 1 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

THE LESSONS OF WORTHY LIVES.—Several well-known figures have recently been taken from the London medical profession by death. Among them may be specially mentioned Dr. Habershon, Dr. King Chambers, Mr. Walter Coulson, and Dr. Lawrence Cumberbatch. Dr. Habershon was for twenty-six years a member of the medical staff of Guy's Hospital. In 1880, being then senior physician, he resigned his appointment, as a protest against the way in which the nursing arrangements at the hospital were carried out by the treasurer in opposition to the expressed views of the staff. By thus resigning Dr. Habershon sustained a considerable pecuniary loss, as, although the hospital appointment was not a paid office, the fees from students for clinical teaching amounted to several hundred pounds a year. Mr. Cooper Forster, the then senior surgeon, resigned at the same time. In consequence of their action, neither he nor Dr. Habershon were elected members of the consulting staff. Dr. Habershon's published writings were chiefly on diseases of the stomach and abdomen, and it is remarkable that he himself died from repeated attacks of hæmatemesis, which was, on post-mortem examination, found to be due to simple ulcer of the stomach. Any mention of him would be incomplete without stating that from early life he took an active interest in religious and philanthropic work of various kinds. Dr. King Chambers was at the time of his death the senior consulting physician to St. Mary's Hospital. Dr. Chambers' career was a remarkable example of the triumph of will over bodily weakness and pain. He suffered for many years from aneurism, for which one of his legs was amputated. He continued to practice, however, and even remained on the teaching staff of St. Mary's Hospital Medical School (as joint lecturer on medicine) after he had ceased to be on the active staff of the hospital. His lectures were always interesting, and delivered in an effective manner, although he depended largely on his copious notes and lectured sitting in a chair. It is by his writings he will chiefly be remembered, combining as they did sound instruction with a polish of style rarely met with in medical works. His "Manual of Diet" was perhaps his most popular work. The return of the disease in the opposite limb compelled Dr. Chambers to retire from active work eleven years ago. Pressure was successful in effecting a cure, but he never resumed practice. At the end of last year aneurisms developed in connection with both carotid arteries, and, in conjunction with cardiac disease, led to his death. Mr. Walter Coulson, who died recently, at the age of fifty-five, had the advantages of both health and fortune to assist him. His uncle was one of the original members of the surgical staff of St. Mary's Hospital, and Mr. Walter Coulson became assistant surgeon at that institution. This appointment, however, he soon vacated in consequence of differences with his colleagues respecting his connection with St. Peter's Hospital, which he was instrumental in founding. At that date there was great opposition to special hospitals, and, piqued by the cold shoulder shown him, Mr. Coulson resigned and appealed to the governors for re-election. He was defeated by a small majority. But he continued his work at St. Peter's Hospital, and acquired no inconsiderable reputation as an authority on diseases of the urinary organs, to which he devoted himself during the past quarter of a century. His association with his uncle, Mr. W. Coulson, doubtless contributed to this result, and not only did his uncle assist him in practice, but at his death left his fortune between Mr. Walter Coulson and another nephew. As this was estimated to be between two and three hundred thousand pounds, Mr. Walter Coulson was thereby rendered independent of practice; but he preferred work, and continued in active practice, although not needing the fees it brought in. Dr. Cumberbatch was an excellent illustration of the fact that a man may attain not only success in practice and pecuniary rewards for his labor, but also no inconsiderable degree of professional reputation while toiling in the humbler walks of the profession. Dr. (then Mr.) Cumberbatch commenced practice in London about forty years ago as a general practitioner. His success was marked, and he became known to a wide circle at the West End. His opinion was especially sought in midwifery cases; so much so that in time he acquired almost a consulting practice in that department. He did, in fact,

become a physician in 1866 by becoming a member of the Royal College of Physicians, but he held no hospital or dispensary appointment.

A Real Elixir of Youth.—A physician writes to *The Lancet* as follows: "When the season began in May last, a veteran aged sixty, I thought that my tennis days were nearly numbered. A walk of four or five miles tired me. Aching and burning in my great-toe joints made walking somewhat painful. I had had rheumatism in my right shoulder for months, so that I was kept awake at night; acute pain at the insertion of the right deltoid accompanied elevation of the arm, and the left shoulder was also uncomfortable. My first day's practice at tennis was disheartening. I could scarcely serve over the net (underhand). My strokes were extremely feeble, and an overhead stroke caused agony at the insertion of the deltoid. Nevertheless I persevered, and by the end of May, after several good warmings at tennis, I lost all my pains, my joints were freer, I could run about with less aching of the feet, my strokes were more severe, and I could elevate my arm for an overhead stroke without pain. After another month's practice, playing two or three times only in the week, so as not to tire the arm too much, I was fit for tournament play, and I ended the season with winning, early in September, an open veterans' singles event. The pleasant exercise and exertion of tennis, taken in moderation, not only drove away my stiffness, my threatened rheumatism, and improved my muscular system so that I could walk fifteen miles a day, or play six or eight sets of tennis in an afternoon without undue fatigue; but it cleared my mental faculties, strengthened my perceptions, gave me a better "grasp of the situation," and rendered me more alert in my ordinary work. I still look forward to the enjoyment of future seasons and coming tournaments. A game that will thus renovate a veteran is invaluable from a medical point of view. If used with discretion, it is to the busy man more available and of greater advantage to keep him in condition than cricket, football, or any other game I know, and the accidents that happen to players of lawn tennis are very few, and not of a serious character."

A Simple Inhaler.—Dr. E. E. Maddox writes to the *Practitioner* as follows: "It may be useful to others to mention the following very simple mode of inhaling volatile remedies, such as pumiline, menthol, eucalyptus, etc., for the relief of some affections of the throat and lungs. Coil a piece of paper into the shape of a cigarette, and fix it with gum. Then insert into one end a small uncompressed piece of absorbent cotton-wool, upon which a drop or two of the desired medicament has been poured. Air is now drawn through the tube by the patient, who holds the other end between his lips. This plan is by many patients, especially by men, preferred to the use of any form of respirator, or to inhalations mingled with steam. These last, moreover, have a relaxing effect in some atonic conditions of the throat. Of a number of remedies, including menthol, inhaled in this way by a patient suffering from pulmonary phthisis, I found that oil of peppermint gave most satisfaction. A small tube of vulcanite flattened like a cigarette-holder at one end, with a raised flange or border to be held within the lips, would doubtless answer still better; but an inhaler, which when needed can be made on the spot, has advantages of its own."

Reading in Bed.—Some credit is doubtless due to those who, in despair of a cure for sleeplessness, have sought to palliate the mischief done to health by reading in bed in order to procure sleep. Their position is at best that of mere necessitarians. The advice they offer may, however, have some value for those who from some cause are physically unable to fall asleep within a reasonable time, and who will insist on reading till they do. It includes various measures intended to prevent or diminish the ocular strain thus incurred. Bathing the eyes with weak salt solution, the adoption of a sitting posture, and the use of sufficiently bright light are among the means advised. They ought certainly to check the bad effects of an unhealthy practice. We should have more sympathy, however, with any attempt to deal with the true source of mischief—the habit itself. This is in a large majority of cases unjustified by any real necessity. Whatever the cause of sleeplessness, whether an idle preceding day, a midday or evening nap, an empty stomach or an over-full one, fatigue or worry, the truest wisdom consists in removing this by the needful change of custom. All rules of treatment, such as those above stated, maintain the reading habit while they moderate its consequences. This is our one objection to them. If sleep requires to be wooed, it should be remembered that there are available, besides the treatment of causal conditions, various direct methods of diverting the mind from the outer world, and thus of inducing sleep. The use of one or other of these is, from their nature, more rational than the practice of reading in bed.—*The Lancet.*

The Construction of a New Bladder After Excision.—At the Surgical Congress recently held at Bologna, Professor G. Tizzoni, of the University of that city, and A. Poggi, gave an account of some experiments they had made on dogs, with the view of ascertaining whether the bladder could be removed and an efficient substitute constructed by operation. First of all laparotomy was performed, and a loop of small intestine about 7 centimetres in length, with its mesentery attached, was isolated by two transverse cuts, washed out with a carbolized solution, and tied at both ends, one extremity being fixed in front of the neck of the bladder. The two ends of the divided gut were then stitched accurately together by circular suture. The dog soon recovered from the operation, and a month later the second stage of the experiment was performed. The ureters were separated from the bladder, and the latter was completely removed. The loop of intestine destined to be the new bladder was then cut across at the lower end and stitched to the neck of the bladder. The ureters were then turned into the artificial bladder. A slender elastic drainage-tube was placed in the urethra to carry off the urine during the first few days. The animal recovered perfectly, and gradually acquired control over its new bladder, and when shown to the Congress, two months later, showed no sign of incontinence. The operation has been repeated with success on several other animals, and Drs. Tizzoni and Poggi are hopeful that it may be applicable to the human subject.—*Medical Recorder.*

The Danger of "Tip-cat."—The following remarks of *The Lancet* are as appropriate for New York as for London, as many of our readers can doubtless aver from personal experience: It may be thought that a game which is one of the most familiar amusements of childhood hardly merits the formality of police regulation. "Tip-cat," however, is by no means unworthy of this distinction. Its value as a pastime is utterly insignificant, but its mischievous effects on the persons of passers-by have become too common to be overlooked. The game as played by children in the street is dangerous in its very nature. No one who has come upon a knot of youngsters thus engaged can have any doubt on this point. It is enough to see the pointed "cat" lightly tipped up from the ground, and the mere attempt to strike it away at random, in order to realize very vividly the fact that one's eyesight in the presence of "tip-cat" is a very precarious possession. The experience of ophthalmic surgeons goes to show that injuries to the eye from this cause are far from uncommon. When, moreover, it is recognized that the results of injuries thus inflicted are likely to be of the most serious character, it will be evident that the public are fully entitled to call for the restriction, and even the prohibition, of this objectionable form of street amusement.

### DISINFECTION OF DWELLINGS BY MEANS OF SULPHUR DIOXIDE.[1]

BY CYRUS EDSON, M.D.,

CHIEF INSPECTOR, HEALTH DEPARTMENT, CITY OF NEW YORK.

WITHIN the past few years numerous experiments have been made by biologists with sulphur dioxide. They have failed in numerous instances to disinfect artificially infected rags and other material subjected to its influence.

These experiments have led biologists to pronounce sulphur dioxide unreliable in its action upon the contagion of disease.

I have had, in my official position, a wide experience with sulphur dioxide as a disinfectant, and I have been led to the conclusion that it is a thorough and an almost perfect destroyer of the infective matter of the acute exanthemata and diphtheria.

The facts that I will place before you in this short paper do not, I am aware, prove perfectly and beyond doubt that $SO_2$ is an absolutely reliable disinfectant. They seem to me to be strong circumstantial evidence in its favor, and I present them as such.

The Disinfecting Corps of the Health Department of the City of New York, during the years 1887 to October 1, 1889, fumigated, by means of $SO_2$ generated from burning sulphur, nearly every room in tenement-houses in our city that had contained cases of small-pox, scarlet fever, diphtheria, or measles. I say *nearly* every case. The aim of the Department was to have the rooms in every case fumigated; but the Corps was a large one, and occasionally a man was found derelict in his duty and had to be discharged, so that wilful neglect in a few instances caused some cases to be neglected. The method of using the sulphur was substantially in accordance with the rules laid down by the Committee on Disinfection of this Association. The sulphur was placed in a shallow iron basin, which was supported in a suitable tub containing water. Ignition was effected by means of about four ounces of alcohol poured over it.

I will take each disease separately, and by comparing the total number of cases with the number of cases that recurred, the recurrence of which could be attributed to infection left after fumigation, show the efficiency of the agent in question.

In the year from October 1, 1887, to October 1, 1888, we had in our city 321 cases of small-pox. These cases occurred in 227 houses. Eighty-two of these cases were contracted from exposure to some of the 239 original cases, nearly all of which were in their turn traced to direct exposure to other cases, either out of the city or in it. Nine cases could not be traced to their cause. They were probably due to contagion from some mild, unrecognized case, that travelled about spreading the disease. Not one single case of the disease was developed from the clothing or from the rooms in which these cases were, and from which they were removed to the hospital for small-pox. No other precaution was taken in the case of the rooms and clothing than that of fumigation by $SO_2$, in proportion of three pounds of sulphur to each one thousand cubic feet of air-space for at least two hours. This, however, was done in a most conscientious and careful manner, immediately after the removal of each case.

Again, in the year from October 1, 1888, to October 1, 1889, 7 cases of small-pox occurred in 5 houses. All were traced to their cause, which was found to be direct exposure to a previous case. Not a single case occurred from infection left in the room or clothing by any of these cases.

We always permit occupancy of rooms that have contained small-pox patients, as soon as they have been fumigated.

In this connection the effect of fumigation by $SO_2$ upon vaccine virus is interesting. On October 2, 1889, ten quill slips, charged with vaccine virus taken from a lot charged equally from the same animal, were exposed in a room $76 \times 15 \times 8$, to the fumes of one pound of sulphur for two hours. Each slip was then used to vaccinate a child that had never before developed vaccinia. All failed to effect any result. Ten other points from the same lot were effective upon all but one child of ten other primary cases. This child evidently had considerable resistance against vaccinia, as it only took after the third trial.

For the purposes of this paper, the same comparison of primary cases with secondary cases, as I have stated was done in cases of small-pox, was made of scarlet fever, diphtheria, and measles in the following streets, which were chosen as examples of the worst, from a sanitary stand-point, in the city: Division Street, Washington Street, Rivington Street, Mulberry Street, West Sixteenth Street, West Twelfth Street, East Seventh Street, East Twelfth Street, East Forty-sixth Street, East 102d Street, and East 113th Street.

Let us first take scarlet fever. From January 1, 1888, to October 1, 1889, 626 cases occurred in the above-named streets in 453 houses, and 135 secondary cases occurred in 87 houses.

Of the 135 secondary cases, 106 occurred within five weeks of the beginning of the primary cases, to the direct contagion of which they were presumably due. This leaves but 29 cases, out of a total of 626, that were possibly due to contagion left in rooms and apartments after disinfection by means of sulphur dioxide after termination of each case.

During the same period (January 1, 1889, to October 1, 1889) 515 cases of diphtheria occurred in 382 houses, and 114 secondary cases occurred in 80 of these houses. Seventy-nine of the secondary cases occurred within four weeks of the beginning of the primary cases, to the direct contagion of which they were, therefore, presumably due. This leaves only 35 cases, out of a total of 515, that were possibly due to contagion of diphtheria left in rooms and apartments after disinfection by means of sulphur dioxide after the termination of each case.

In the case of measles, 557 cases occurred in 361 houses, and 163 secondary cases occurred in 95 of these houses. One hundred and twenty-two of the secondary cases occurred within five weeks of the beginning of the primary cases, to the direct contagion of which they were, therefore, presumably due. This leaves only 41 cases, out of a total of 557, that were possibly due to contagion of measles left on the premises after disinfection by means of sulphur dioxide performed after the termination of each case.

These figures are interesting when carefully considered, and they show the relative efficiency of sulphur dioxide in the case of each of the diseases. The gas is most de-
